

CUDA C BEST PRACTICES GUIDE

DG-05603-001_v5.5 for POWER8 | August 2014

Design Guide

TABLE OF CONTENTS

Preface	vii
What Is This Document?.....	vii
Who Should Read This Guide?.....	vii
Assess, Parallelize, Optimize, Deploy.....	viii
Assess.....	viii
Parallelize.....	ix
Optimize.....	ix
Deploy.....	ix
Recommendations and Best Practices.....	x
Chapter 1. Assessing Your Application	1
Chapter 2. Heterogeneous Computing	2
2.1. Differences between Host and Device.....	2
2.2. What Runs on a CUDA-Enabled Device?.....	3
Chapter 3. Application Profiling	5
3.1. Profile.....	5
3.1.1. Creating the Profile.....	5
3.1.2. Identifying Hotspots.....	6
3.1.3. Understanding Scaling.....	6
3.1.3.1. Strong Scaling and Amdahl's Law.....	6
3.1.3.2. Weak Scaling and Gustafson's Law.....	7
3.1.3.3. Applying Strong and Weak Scaling.....	7
Chapter 4. Parallelizing Your Application	9
Chapter 5. Getting Started	10
5.1. Parallel Libraries.....	10
5.2. Parallelizing Compilers.....	10
5.3. Coding to Expose Parallelism.....	11
Chapter 6. Getting the Right Answer	12
6.1. Verification.....	12
6.1.1. Reference Comparison.....	12
6.1.2. Unit Testing.....	12
6.2. Debugging.....	13
6.3. Numerical Accuracy and Precision.....	13
6.3.1. Single vs. Double Precision.....	13
6.3.2. Floating Point Math Is not Associative.....	14
6.3.3. Promotions to Doubles and Truncations to Floats.....	14
6.3.4. IEEE 754 Compliance.....	14
6.3.5. x86 80-bit Computations.....	15
Chapter 7. Optimizing CUDA Applications	16
Chapter 8. Performance Metrics	17
8.1. Timing.....	17

8.1.1. Using CPU Timers.....	17
8.1.2. Using CUDA GPU Timers.....	18
8.2. Bandwidth.....	18
8.2.1. Theoretical Bandwidth Calculation.....	19
8.2.2. Effective Bandwidth Calculation.....	19
8.2.3. Throughput Reported by Visual Profiler.....	20
Chapter 9. Memory Optimizations.....	21
9.1. Data Transfer Between Host and Device.....	21
9.1.1. Pinned Memory.....	22
9.1.2. Asynchronous and Overlapping Transfers with Computation.....	22
9.1.3. Zero Copy.....	25
9.1.4. Unified Virtual Addressing.....	26
9.2. Device Memory Spaces.....	26
9.2.1. Coalesced Access to Global Memory.....	28
9.2.1.1. A Simple Access Pattern.....	28
9.2.1.2. A Sequential but Misaligned Access Pattern.....	29
9.2.1.3. Effects of Misaligned Accesses.....	30
9.2.1.4. Strided Accesses.....	31
9.2.2. Shared Memory.....	33
9.2.2.1. Shared Memory and Memory Banks.....	33
9.2.2.2. Shared Memory in Matrix Multiplication (C=AB).....	34
9.2.2.3. Shared Memory in Matrix Multiplication (C=AAT).....	38
9.2.3. Local Memory.....	40
9.2.4. Texture Memory.....	40
9.2.4.1. Additional Texture Capabilities.....	40
9.2.5. Constant Memory.....	41
9.2.6. Registers.....	41
9.2.6.1. Register Pressure.....	42
9.3. Allocation.....	42
Chapter 10. Execution Configuration Optimizations.....	43
10.1. Occupancy.....	43
10.1.1. Calculating Occupancy.....	44
10.2. Concurrent Kernel Execution.....	45
10.3. Hiding Register Dependencies.....	46
10.4. Thread and Block Heuristics.....	46
10.5. Effects of Shared Memory.....	47
Chapter 11. Instruction Optimization.....	49
11.1. Arithmetic Instructions.....	49
11.1.1. Division Modulo Operations.....	49
11.1.2. Reciprocal Square Root.....	49
11.1.3. Other Arithmetic Instructions.....	50
11.1.4. Math Libraries.....	50
11.1.5. Precision-related Compiler Flags.....	51

11.2. Memory Instructions.....	52
Chapter 12. Control Flow.....	53
12.1. Branching and Divergence.....	53
12.2. Branch Predication.....	53
12.3. Loop Counters Signed vs. Unsigned.....	54
12.4. Synchronizing Divergent Threads in a Loop.....	54
Chapter 13. Deploying CUDA Applications.....	56
Chapter 14. Understanding the Programming Environment.....	57
14.1. CUDA Compute Capability.....	57
14.2. Additional Hardware Data.....	58
14.3. CUDA Runtime and Driver API Version.....	58
14.4. Which Compute Capability Target.....	59
14.5. CUDA Runtime.....	59
Chapter 15. Preparing for Deployment.....	61
15.1. Testing for CUDA Availability.....	61
15.2. Error Handling.....	62
15.3. Building for Maximum Compatibility.....	62
15.4. Distributing the CUDA Runtime and Libraries.....	63
Chapter 16. Deployment Infrastructure Tools.....	66
16.1. Nvidia-SMI.....	66
16.1.1. Queryable state.....	66
16.1.2. Modifiable state.....	67
16.2. NVML.....	67
16.3. Cluster Management Tools.....	67
16.4. Compiler JIT Cache Management Tools.....	68
16.5. CUDA_VISIBLE_DEVICES.....	68
Appendix A. Recommendations and Best Practices.....	69
A.1. Overall Performance Optimization Strategies.....	69
Appendix B. nvcc Compiler Switches.....	71
B.1. nvcc.....	71

PREFACE

What Is This Document?

This Best Practices Guide is a manual to help developers obtain the best performance from the NVIDIA® CUDA™ architecture using version 5.5 of the CUDA Toolkit. It presents established parallelization and optimization techniques and explains coding metaphors and idioms that can greatly simplify programming for CUDA-capable GPU architectures.

While the contents can be used as a reference manual, you should be aware that some topics are revisited in different contexts as various programming and configuration topics are explored. As a result, it is recommended that first-time readers proceed through the guide sequentially. This approach will greatly improve your understanding of effective programming practices and enable you to better use the guide for reference later.

Who Should Read This Guide?

The discussions in this guide all use the C programming language, so you should be comfortable reading C code.

This guide refers to and relies on several other documents that you should have at your disposal for reference, all of which are available at no cost from the CUDA website <http://developer.nvidia.com/cuda-downloads>. The following documents are especially important resources:

- ▶ *CUDA Getting Started Guide*
- ▶ *CUDA C Programming Guide*
- ▶ *CUDA Toolkit Reference Manual*

In particular, the optimization section of this guide assumes that you have already successfully downloaded and installed the CUDA Toolkit (if not, please refer to the relevant *CUDA Getting Started Guide* for your platform) and that you have a basic familiarity with the CUDA C programming language and environment (if not, please refer to the *CUDA C Programming Guide*).

Assess, Parallelize, Optimize, Deploy

This guide introduces the *Assess, Parallelize, Optimize, Deploy (APOD)* design cycle for applications with the goal of helping application developers to rapidly identify the portions of their code that would most readily benefit from GPU acceleration, rapidly realize that benefit, and begin leveraging the resulting speedups in production as early as possible.

APOD is a cyclical process: initial speedups can be achieved, tested, and deployed with only minimal initial investment of time, at which point the cycle can begin again by identifying further optimization opportunities, seeing additional speedups, and then deploying the even faster versions of the application into production.

Assess

For an existing project, the first step is to assess the application to locate the parts of the code that are responsible for the bulk of the execution time. Armed with this knowledge, the developer can evaluate these bottlenecks for parallelization and start to investigate GPU acceleration.

By understanding the end-user's requirements and constraints and by applying Amdahl's and Gustafson's laws, the developer can determine the upper bound of performance improvement from acceleration of the identified portions of the application.

Parallelize

Having identified the hotspots and having done the basic exercises to set goals and expectations, the developer needs to parallelize the code. Depending on the original code, this can be as simple as calling into an existing GPU-optimized library such as **cuBLAS**, **cuFFT**, or **Thrust**, or it could be as simple as adding a few preprocessor directives as hints to a parallelizing compiler.

On the other hand, some applications' designs will require some amount of refactoring to expose their inherent parallelism. As even future CPU architectures will require exposing this parallelism in order to improve or simply maintain the performance of sequential applications, the CUDA family of parallel programming languages (CUDA C/C++, CUDA Fortran, etc.) aims to make the expression of this parallelism as simple as possible, while simultaneously enabling operation on CUDA-capable GPUs designed for maximum parallel throughput.

Optimize

After each round of application parallelization is complete, the developer can move to optimizing the implementation to improve performance. Since there are many possible optimizations that can be considered, having a good understanding of the needs of the application can help to make the process as smooth as possible. However, as with APOD as a whole, program optimization is an iterative process (identify an opportunity for optimization, apply and test the optimization, verify the speedup achieved, and repeat), meaning that it is not necessary for a programmer to spend large amounts of time memorizing the bulk of all possible optimization strategies prior to seeing good speedups. Instead, strategies can be applied incrementally as they are learned.

Optimizations can be applied at various levels, from overlapping data transfers with computation all the way down to fine-tuning floating-point operation sequences. The available profiling tools are invaluable for guiding this process, as they can help suggest a next-best course of action for the developer's optimization efforts and provide references into the relevant portions of the optimization section of this guide.

Deploy

Having completed the GPU acceleration of one or more components of the application it is possible to compare the outcome with the original expectation. Recall that the initial *assess* step allowed the developer to determine an upper bound for the potential speedup attainable by accelerating given hotspots.

Before tackling other hotspots to improve the total speedup, the developer should consider taking the partially parallelized implementation and carry it through to production. This is important for a number of reasons; for example, it allows the user to profit from their investment as early as possible (the speedup may be partial but is still valuable), and it minimizes risk for the developer and the user by providing an evolutionary rather than revolutionary set of changes to the application.

Recommendations and Best Practices

Throughout this guide, specific recommendations are made regarding the design and implementation of CUDA C code. These recommendations are categorized by priority, which is a blend of the effect of the recommendation and its scope. Actions that present substantial improvements for most CUDA applications have the highest priority, while small optimizations that affect only very specific situations are given a lower priority.

Before implementing lower priority recommendations, it is good practice to make sure all higher priority recommendations that are relevant have already been applied. This approach will tend to provide the best results for the time invested and will avoid the trap of premature optimization.

The criteria of benefit and scope for establishing priority will vary depending on the nature of the program. In this guide, they represent a typical case. Your code might reflect different priority factors. Regardless of this possibility, it is good practice to verify that no higher-priority recommendations have been overlooked before undertaking lower-priority items.

Code samples throughout the guide omit error checking for conciseness. Production code should, however, systematically check the error code returned by each API call and check for failures in kernel launches by calling `cudaGetLastError()`.

Chapter 1.

ASSESSING YOUR APPLICATION

From supercomputers to mobile phones, modern processors increasingly rely on parallelism to provide performance. The core computational unit, which includes control, arithmetic, registers and typically some cache, is replicated some number of times and connected to memory via a network. As a result, all modern processors require parallel code in order to achieve good utilization of their computational power.

While processors are evolving to expose more fine-grained parallelism to the programmer, many existing applications have evolved either as serial codes or as coarse-grained parallel codes (for example, where the data is decomposed into regions processed in parallel, with sub-regions shared using MPI). In order to profit from any modern processor architecture, GPUs included, the first steps are to assess the application to identify the hotspots, determine whether they can be parallelized, and understand the relevant workloads both now and in the future.

Chapter 2.

HETEROGENEOUS COMPUTING

CUDA programming involves running code on two different platforms concurrently: a *host* system with one or more CPUs and one or more CUDA-enabled NVIDIA GPU *devices*.

While NVIDIA GPUs are frequently associated with graphics, they are also powerful arithmetic engines capable of running thousands of lightweight threads in parallel. This capability makes them well suited to computations that can leverage parallel execution.

However, the device is based on a distinctly different design from the host system, and it's important to understand those differences and how they determine the performance of CUDA applications in order to use CUDA effectively.

2.1. Differences between Host and Device

The primary differences are in threading model and in separate physical memories:

Threading resources

Execution pipelines on host systems can support a limited number of concurrent threads. Servers that have four hex-core processors today can run only 24 threads concurrently (or 48 if the CPUs support Hyper-Threading.) By comparison, the *smallest* executable unit of parallelism on a CUDA device comprises 32 threads (termed a *warp* of threads). Modern NVIDIA GPUs can support up to 1536 active threads concurrently per multiprocessor (see *Features and Specifications* of the *CUDA C Programming Guide*) On GPUs with 16 multiprocessors, this leads to more than 24,000 concurrently active threads.

Threads

Threads on a CPU are generally heavyweight entities. The operating system must swap threads on and off CPU execution channels to provide multithreading capability. Context switches (when two threads are swapped) are therefore slow and expensive. By comparison, threads on GPUs are extremely lightweight. In a typical system, thousands of threads are queued up for work (in warps of 32 threads each). If the GPU must wait on one warp of threads, it simply begins executing work on another. Because separate registers are allocated to all active threads, no swapping of registers or other state need occur when switching among GPU threads. Resources stay allocated to each thread until it completes its execution. In short, CPU cores are

designed to *minimize latency* for one or two threads at a time each, whereas GPUs are designed to handle a large number of concurrent, lightweight threads in order to *maximize throughput*.

RAM

The host system and the device each have their own distinct attached physical memories. As the host and device memories are separated by the PCI Express (PCIe) bus, items in the host memory must occasionally be communicated across the bus to the device memory or vice versa as described in [What Runs on a CUDA-Enabled Device?](#)

These are the primary hardware differences between CPU hosts and GPU devices with respect to parallel programming. Other differences are discussed as they arise elsewhere in this document. Applications composed with these differences in mind can treat the host and device together as a cohesive heterogeneous system wherein each processing unit is leveraged to do the kind of work it does best: sequential work on the host and parallel work on the device.

2.2. What Runs on a CUDA-Enabled Device?

The following issues should be considered when determining what parts of an application to run on the device:

- ▶ The device is ideally suited for computations that can be run on numerous data elements simultaneously in parallel. This typically involves arithmetic on large data sets (such as matrices) where the same operation can be performed across thousands, if not millions, of elements at the same time. This is a requirement for good performance on CUDA: the software must use a large number (generally thousands or tens of thousands) of concurrent threads. The support for running numerous threads in parallel derives from CUDA's use of a lightweight threading model described above.
- ▶ For best performance, there should be some coherence in memory access by adjacent threads running on the device. Certain memory access patterns enable the hardware to coalesce groups of reads or writes of multiple data items into one operation. Data that cannot be laid out so as to enable *coalescing*, or that doesn't have enough locality to use the L1 or texture caches effectively, will tend to see lesser speedups when used in computations on CUDA.
- ▶ To use CUDA, data values must be transferred from the host to the device along the PCI Express (PCIe) bus. These transfers are costly in terms of performance and should be minimized. (See [Data Transfer Between Host and Device](#).) This cost has several ramifications:
 - ▶ The complexity of operations should justify the cost of moving data to and from the device. Code that transfers data for brief use by a small number of threads will see little or no performance benefit. The ideal scenario is one in which many threads perform a substantial amount of work.

For example, transferring two matrices to the device to perform a matrix addition and then transferring the results back to the host will not realize much performance benefit. The issue here is the number of operations performed per

data element transferred. For the preceding procedure, assuming matrices of size $N \times N$, there are N^2 operations (additions) and $3N^2$ elements transferred, so the ratio of operations to elements transferred is 1:3 or $O(1)$. Performance benefits can be more readily achieved when this ratio is higher. For example, a matrix multiplication of the same matrices requires N^3 operations (multiply-add), so the ratio of operations to elements transferred is $O(N)$, in which case the larger the matrix the greater the performance benefit. The types of operations are an additional factor, as additions have different complexity profiles than, for example, trigonometric functions. It is important to include the overhead of transferring data to and from the device in determining whether operations should be performed on the host or on the device.

- Data should be kept on the device as long as possible. Because transfers should be minimized, programs that run multiple kernels on the same data should favor leaving the data on the device between kernel calls, rather than transferring intermediate results to the host and then sending them back to the device for subsequent calculations. So, in the previous example, had the two matrices to be added already been on the device as a result of some previous calculation, or if the results of the addition would be used in some subsequent calculation, the matrix addition should be performed locally on the device. This approach should be used even if one of the steps in a sequence of calculations could be performed faster on the host. Even a relatively slow kernel may be advantageous if it avoids one or more PCIe transfers. [Data Transfer Between Host and Device](#) provides further details, including the measurements of bandwidth between the host and the device versus within the device proper.

Chapter 3.

APPLICATION PROFILING

3.1. Profile

Many codes accomplish a significant portion of the work with a relatively small amount of code. Using a profiler, the developer can identify such hotspots and start to compile a list of candidates for parallelization.

3.1.1. Creating the Profile

There are many possible approaches to profiling the code, but in all cases the objective is the same: to identify the function or functions in which the application is spending most of its execution time.

High Priority: To maximize developer productivity, profile the application to determine hotspots and bottlenecks.

The most important consideration with any profiling activity is to ensure that the workload is realistic - i.e., that information gained from the test and decisions based upon that information are relevant to real data. Using unrealistic workloads can lead to sub-optimal results and wasted effort both by causing developers to optimize for unrealistic problem sizes and by causing developers to concentrate on the wrong functions.

There are a number of tools that can be used to generate the profile. The following example is based on **gprof**, which is an open-source profiler for Linux platforms from the GNU Binutils collection.

```
$ gcc -O2 -g -pg myprog.c
$ gprof ./a.out > profile.txt
Each sample counts as 0.01 seconds.
```

	%	cumulative	self		self	total	
time	seconds	seconds	calls	ms/call	ms/call	name	
33.34	0.02	0.02	7208	0.00	0.00	genTimeStep

0.00	0.06	0.00	1	0.00	0.00	profil
0.00	0.06	0.00	1	0.00	50.00	report

3.1.2. Identifying Hotspots

In the example above, we can clearly see that the function `genTimeStep()` takes one-third of the total running time of the application. This should be our first candidate function for parallelization. [Understanding Scaling](#) discusses the potential benefit we might expect from such parallelization.

It is worth noting that several of the other functions in the above example also take up a significant portion of the overall running time, such as `calcStats()` and `calcSummaryData()`. Parallelizing these functions as well should increase our speedup potential. However, since APOD is a cyclical process, we might opt to parallelize these functions in a subsequent APOD pass, thereby limiting the scope of our work in any given pass to a smaller set of incremental changes.

3.1.3. Understanding Scaling

The amount of performance benefit an application will realize by running on CUDA depends entirely on the extent to which it can be parallelized. Code that cannot be sufficiently parallelized should run on the host, unless doing so would result in excessive transfers between the host and the device.

High Priority: To get the maximum benefit from CUDA, focus first on finding ways to parallelize sequential code.

By understanding how applications can scale it is possible to set expectations and plan an incremental parallelization strategy. [Strong Scaling and Amdahl's Law](#) describes strong scaling, which allows us to set an upper bound for the speedup with a fixed problem size. [Weak Scaling and Gustafson's Law](#) describes weak scaling, where the speedup is attained by growing the problem size. In many applications, a combination of strong and weak scaling is desirable.

3.1.3.1. Strong Scaling and Amdahl's Law

Strong scaling is a measure of how, for a fixed overall problem size, the time to solution decreases as more processors are added to a system. An application that exhibits linear strong scaling has a speedup equal to the number of processors used.

Strong scaling is usually equated with Amdahl's Law, which specifies the maximum speedup that can be expected by parallelizing portions of a serial program. Essentially, it states that the maximum speedup S of a program is:

$$S = \frac{1}{(1-P) + \frac{P}{N}}$$

Here P is the fraction of the total serial execution time taken by the portion of code that can be parallelized and N is the number of processors over which the parallel portion of the code runs.

The larger N is (that is, the greater the number of processors), the smaller the P/N fraction. It can be simpler to view N as a very large number, which essentially transforms the equation into $S = 1/(1-P)$. Now, if 3/4 of the running time of a sequential program is parallelized, the maximum speedup over serial code is $1 / (1 - 3/4) = 4$.

In reality, most applications do not exhibit perfectly linear strong scaling, even if they do exhibit some degree of strong scaling. For most purposes, the key point is that the larger the parallelizable portion P is, the greater the potential speedup. Conversely, if P is a small number (meaning that the application is not substantially parallelizable), increasing the number of processors N does little to improve performance. Therefore, to get the largest speedup for a fixed problem size, it is worthwhile to spend effort on increasing P , maximizing the amount of code that can be parallelized.

3.1.3.2. Weak Scaling and Gustafson's Law

Weak scaling is a measure of how the time to solution changes as more processors are added to a system with a fixed problem size *per processor*; i.e., where the overall problem size increases as the number of processors is increased.

Weak scaling is often equated with Gustafson's Law, which states that in practice, the problem size scales with the number of processors. Because of this, the maximum speedup S of a program is:

$$S = N + (1-P)(N-1)$$

Here P is the fraction of the total serial execution time taken by the portion of code that can be parallelized and N is the number of processors over which the parallel portion of the code runs.

Another way of looking at Gustafson's Law is that it is not the problem size that remains constant as we scale up the system but rather the execution time. Note that Gustafson's Law assumes that the ratio of serial to parallel execution remains constant, reflecting additional cost in setting up and handling the larger problem.

3.1.3.3. Applying Strong and Weak Scaling

Understanding which type of scaling is most applicable to an application is an important part of estimating speedup. For some applications the problem size will remain constant and hence only strong scaling is applicable. An example would be modeling how two molecules interact with each other, where the molecule sizes are fixed.

For other applications, the problem size will grow to fill the available processors. Examples include modeling fluids or structures as meshes or grids and some Monte Carlo simulations, where increasing the problem size provides increased accuracy.

Having understood the application profile, the developer should understand how the problem size would change if the computational performance changes and then apply either Amdahl's or Gustafson's Law to determine an upper bound for the speedup.

Chapter 4.

PARALLELIZING YOUR APPLICATION

Having identified the hotspots and having done the basic exercises to set goals and expectations, the developer needs to parallelize the code. Depending on the original code, this can be as simple as calling into an existing GPU-optimized library such as **cuBLAS**, **cuFFT**, or **Thrust**, or it could be as simple as adding a few preprocessor directives as hints to a parallelizing compiler.

On the other hand, some applications' designs will require some amount of refactoring to expose their inherent parallelism. As even future CPU architectures will require exposing this parallelism in order to improve or simply maintain the performance of sequential applications, the CUDA family of parallel programming languages (CUDA C/C++, CUDA Fortran, etc.) aims to make the expression of this parallelism as simple as possible, while simultaneously enabling operation on CUDA-capable GPUs designed for maximum parallel throughput.

Chapter 5.

GETTING STARTED

There are several key strategies for parallelizing sequential code. While the details of how to apply these strategies to a particular application is a complex and problem-specific topic, the general themes listed here apply regardless of whether we are parallelizing code to run on for multicore CPUs or for use on CUDA GPUs.

5.1. Parallel Libraries

The most straightforward approach to parallelizing an application is to leverage existing libraries that take advantage of parallel architectures on our behalf. The CUDA Toolkit includes a number of such libraries that have been fine-tuned for NVIDIA CUDA GPUs, such as **cuBLAS**, **cuFFT**, and so on.

The key here is that libraries are most useful when they match well with the needs of the application. Applications already using other BLAS libraries can often quite easily switch to **cuBLAS**, for example, whereas applications that do little to no linear algebra will have little use for **cuBLAS**. The same goes for other CUDA Toolkit libraries: **cuFFT** has an interface similar to that of **FFTW**, etc.

Also of note is the Thrust library, which is a parallel C++ template library similar to the C++ Standard Template Library. Thrust provides a rich collection of data parallel primitives such as scan, sort, and reduce, which can be composed together to implement complex algorithms with concise, readable source code. By describing your computation in terms of these high-level abstractions you provide Thrust with the freedom to select the most efficient implementation automatically. As a result, Thrust can be utilized in rapid prototyping of CUDA applications, where programmer productivity matters most, as well as in production, where robustness and absolute performance are crucial.

5.2. Parallelizing Compilers

Another common approach to parallelization of sequential codes is to make use of parallelizing compilers. Often this means the use of directives-based approaches, where the programmer uses a pragma or other similar notation to provide hints to the compiler about where parallelism can be found without needing to modify or adapt

the underlying code itself. By exposing parallelism to the compiler, directives allow the compiler to do the detailed work of mapping the computation onto the parallel architecture.

The OpenACC standard provides a set of compiler directives to specify loops and regions of code in standard C, C++ and Fortran that should be offloaded from a host CPU to an attached accelerator such as a CUDA GPU. The details of managing the accelerator device are handled implicitly by an OpenACC-enabled compiler and runtime.

See <http://www.openacc.org/> for details.

5.3. Coding to Expose Parallelism

For applications that need additional functionality or performance beyond what existing parallel libraries or parallelizing compilers can provide, parallel programming languages such as CUDA C/C++ that integrate seamlessly with existing sequential code are essential.

Once we have located a hotspot in our application's profile assessment and determined that custom code is the best approach, we can use CUDA C/C++ to expose the parallelism in that portion of our code as a CUDA kernel. We can then launch this kernel onto the GPU and retrieve the results without requiring major rewrites to the rest of our application.

This approach is most straightforward when the majority of the total running time of our application is spent in a few relatively isolated portions of the code. More difficult to parallelize are applications with a very flat profile - i.e., applications where the time spent is spread out relatively evenly across a wide portion of the code base. For the latter variety of application, some degree of code refactoring to expose the inherent parallelism in the application might be necessary, but keep in mind that this refactoring work will tend to benefit all future architectures, CPU and GPU alike, so it is well worth the effort should it become necessary.

Chapter 6.

GETTING THE RIGHT ANSWER

Obtaining the right answer is clearly the principal goal of all computation. On parallel systems, it is possible to run into difficulties not typically found in traditional serial-oriented programming. These include threading issues, unexpected values due to the way floating-point values are computed, and challenges arising from differences in the way CPU and GPU processors operate. This chapter examines issues that can affect the correctness of returned data and points to appropriate solutions.

6.1. Verification

6.1.1. Reference Comparison

A key aspect of correctness verification for modifications to any existing program is to establish some mechanism whereby previous known-good reference outputs from representative inputs can be compared to new results. After each change is made, ensure that the results match using whatever criteria apply to the particular algorithm. Some will expect bitwise identical results, which is not always possible, especially where floating-point arithmetic is concerned; see [Numerical Accuracy and Precision](#) regarding numerical accuracy. For other algorithms, implementations may be considered correct if they match the reference within some small epsilon.

Note that the process used for validating numerical results can easily be extended to validate performance results as well. We want to ensure that each change we make is correct *and* that it improves performance (and by how much). Checking these things frequently as an integral part of our cyclical APOD process will help ensure that we achieve the desired results as rapidly as possible.

6.1.2. Unit Testing

A useful counterpart to the reference comparisons described above is to structure the code itself in such a way that is readily verifiable at the unit level. For example, we can write our CUDA kernels as a collection of many short `__device__` functions rather than one large monolithic `__global__` function; each device function can be tested independently before hooking them all together.

For example, many kernels have complex addressing logic for accessing memory in addition to their actual computation. If we validate our addressing logic separately prior to introducing the bulk of the computation, then this will simplify any later debugging efforts. (Note that the CUDA compiler considers any device code that does not contribute to a write to global memory as dead code subject to elimination, so we must at least write *something* out to global memory as a result of our addressing logic in order to successfully apply this strategy.)

Going a step further, if most functions are defined as `__host__ __device__` rather than just `__device__` functions, then these functions can be tested on both the CPU and the GPU, thereby increasing our confidence that the function is correct and that there will not be any unexpected differences in the results. If there *are* differences, then those differences will be seen early and can be understood in the context of a simple function.

As a useful side effect, this strategy will allow us a means to reduce code duplication should we wish to include both CPU and GPU execution paths in our application: if the bulk of the work of our CUDA kernels is done in `__host__ __device__` functions, we can easily call those functions from both the host code *and* the device code without duplication.

6.2. Debugging

CUDA-GDB is a port of the GNU Debugger that runs on Linux and Mac; see: <http://developer.nvidia.com/cuda-gdb>.

The NVIDIA Parallel Nsight debugging and profiling tool for Microsoft Windows Vista and Windows 7 is available as a free plugin for Microsoft Visual Studio; see: <http://developer.nvidia.com/nvidia-parallel-nsight>.

Several third-party debuggers now support CUDA debugging as well; see: <http://developer.nvidia.com/debugging-solutions> for more details.

6.3. Numerical Accuracy and Precision

Incorrect or unexpected results arise principally from issues of floating-point accuracy due to the way floating-point values are computed and stored. The following sections explain the principal items of interest. Other peculiarities of floating-point arithmetic are presented in *Features and Technical Specifications* of the *CUDA C Programming Guide* as well as in a whitepaper and accompanying webinar on floating-point precision and performance available from <http://developer.nvidia.com/content/precision-performance-floating-point-and-ieee-754-compliance-nvidia-gpus>.

6.3.1. Single vs. Double Precision

Devices of [compute capability](#) 1.3 and higher provide native support for double-precision floating-point values (that is, values 64 bits wide). Results obtained using double-precision arithmetic will frequently differ from the same operation performed via single-precision arithmetic due to the greater precision of the former and due to rounding issues. Therefore, it is important to be sure to compare values of like precision

and to express the results within a certain tolerance rather than expecting them to be exact.

Whenever doubles are used, use at least the `-arch=sm_13` switch on the `nvcc` command line; see *PTX Compatibility* and *Application Compatibility* of the *CUDA C Programming Guide* for more details.

6.3.2. Floating Point Math Is not Associative

Each floating-point arithmetic operation involves a certain amount of rounding. Consequently, the order in which arithmetic operations are performed is important. If A , B , and C are floating-point values, $(A+B)+C$ is not guaranteed to equal $A+(B+C)$ as it is in symbolic math. When you parallelize computations, you potentially change the order of operations and therefore the parallel results might not match sequential results. This limitation is not specific to CUDA, but an inherent part of parallel computation on floating-point values.

6.3.3. Promotions to Doubles and Truncations to Floats

When comparing the results of computations of float variables between the host and device, make sure that promotions to double precision on the host do not account for different numerical results. For example, if the code segment

```
float a;
...
a = a*1.02;
```

were performed on a device of [compute capability](#) 1.2 or less, or on a device with compute capability 1.3 but compiled without enabling double precision (as mentioned above), then the multiplication would be performed in single precision. However, if the code were performed on the host, the literal `1.02` would be interpreted as a double-precision quantity and `a` would be promoted to a double, the multiplication would be performed in double precision, and the result would be truncated to a float - thereby yielding a slightly different result. If, however, the literal `1.02f` were replaced with `1.02f`, the result would be the same in all cases because no promotion to doubles would occur. To ensure that computations use single-precision arithmetic, always use float literals.

In addition to accuracy, the conversion between doubles and floats (and vice versa) has a detrimental effect on performance, as discussed in [Instruction Optimization](#).

6.3.4. IEEE 754 Compliance

All CUDA compute devices follow the IEEE 754 standard for binary floating-point representation, with some small exceptions. These exceptions, which are detailed in *Features and Technical Specifications* of the *CUDA C Programming Guide*, can lead to results that differ from IEEE 754 values computed on the host system.

One of the key differences is the fused multiply-add (FMA) instruction, which combines multiply-add operations into a single instruction execution. Its result will often differ slightly from results obtained by doing the two operations separately.

6.3.5. x86 80-bit Computations

x86 processors can use an 80-bit *double extended precision* math when performing floating-point calculations. The results of these calculations can frequently differ from pure 64-bit operations performed on the CUDA device. To get a closer match between values, set the x86 host processor to use regular double or single precision (64 bits and 32 bits, respectively). This is done with the **FLDCW** x86 assembly instruction or the equivalent operating system API.

Chapter 7.

OPTIMIZING CUDA APPLICATIONS

After each round of application parallelization is complete, the developer can move to optimizing the implementation to improve performance. Since there are many possible optimizations that can be considered, having a good understanding of the needs of the application can help to make the process as smooth as possible. However, as with APOD as a whole, program optimization is an iterative process (identify an opportunity for optimization, apply and test the optimization, verify the speedup achieved, and repeat), meaning that it is not necessary for a programmer to spend large amounts of time memorizing the bulk of all possible optimization strategies prior to seeing good speedups. Instead, strategies can be applied incrementally as they are learned.

Optimizations can be applied at various levels, from overlapping data transfers with computation all the way down to fine-tuning floating-point operation sequences. The available profiling tools are invaluable for guiding this process, as they can help suggest a next-best course of action for the developer's optimization efforts and provide references into the relevant portions of the optimization section of this guide.

Chapter 8.

PERFORMANCE METRICS

When attempting to optimize CUDA code, it pays to know how to measure performance accurately and to understand the role that bandwidth plays in performance measurement. This chapter discusses how to correctly measure performance using CPU timers and CUDA events. It then explores how bandwidth affects performance metrics and how to mitigate some of the challenges it poses.

8.1. Timing

CUDA calls and kernel executions can be timed using either CPU or GPU timers. This section examines the functionality, advantages, and pitfalls of both approaches.

8.1.1. Using CPU Timers

Any CPU timer can be used to measure the elapsed time of a CUDA call or kernel execution. The details of various CPU timing approaches are outside the scope of this document, but developers should always be aware of the resolution their timing calls provide.

When using CPU timers, it is critical to remember that many CUDA API functions are asynchronous; that is, they return control back to the calling CPU thread prior to completing their work. All kernel launches are asynchronous, as are memory-copy functions with the **Async** suffix on their names. Therefore, to accurately measure the elapsed time for a particular call or sequence of CUDA calls, it is necessary to synchronize the CPU thread with the GPU by calling **cudaDeviceSynchronize()** immediately before starting and stopping the CPU timer. **cudaDeviceSynchronize()** blocks the calling CPU thread until all CUDA calls previously issued by the thread are completed.

Although it is also possible to synchronize the CPU thread with a particular stream or event on the GPU, these synchronization functions are not suitable for timing code in streams other than the default stream. **cudaStreamSynchronize()** blocks the CPU thread until all CUDA calls previously issued into the given stream have completed. **cudaEventSynchronize()** blocks until a given event in a particular stream has been

recorded by the GPU. Because the driver may interleave execution of CUDA calls from other non-default streams, calls in other streams may be included in the timing.

Because the default stream, stream 0, exhibits serializing behavior for work on the device (an operation in the default stream can begin only after all preceding calls in any stream have completed; and no subsequent operation in any stream can begin until it finishes), these functions can be used reliably for timing in the default stream.

Be aware that CPU-to-GPU synchronization points such as those mentioned in this section imply a stall in the GPU's processing pipeline and should thus be used sparingly to minimize their performance impact.

8.1.2. Using CUDA GPU Timers

The CUDA event API provides calls that create and destroy events, record events (via timestamp), and convert timestamp differences into a floating-point value in milliseconds. [How to time code using CUDA events](#) illustrates their use.

How to time code using CUDA events

```
cudaEvent_t start, stop;
float time;

cudaEventCreate(&start);
cudaEventCreate(&stop);

cudaEventRecord( start, 0 );
kernel<<<grid,threads>>> ( d_odata, d_idata, size_x, size_y,
                           NUM_REPS);
cudaEventRecord( stop, 0 );
cudaEventSynchronize( stop );

cudaEventElapsedTime( &time, start, stop );
cudaEventDestroy( start );
cudaEventDestroy( stop );
```

Here **cudaEventRecord()** is used to place the **start** and **stop** events into the default stream, stream 0. The device will record a timestamp for the event when it reaches that event in the stream. The **cudaEventElapsedTime()** function returns the time elapsed between the recording of the **start** and **stop** events. This value is expressed in milliseconds and has a resolution of approximately half a microsecond. Like the other calls in this listing, their specific operation, parameters, and return values are described in the *CUDA Toolkit Reference Manual*. Note that the timings are measured on the GPU clock, so the timing resolution is operating-system-independent.

8.2. Bandwidth

Bandwidth - the rate at which data can be transferred - is one of the most important gating factors for performance. Almost all changes to code should be made in the context of how they affect bandwidth. As described in [Memory Optimizations](#) of this guide, bandwidth can be dramatically affected by the choice of memory in which data is stored, how the data is laid out and the order in which it is accessed, as well as other factors.

To measure performance accurately, it is useful to calculate theoretical and effective bandwidth. When the latter is much lower than the former, design or implementation details are likely to reduce bandwidth, and it should be the primary goal of subsequent optimization efforts to increase it.

High Priority: Use the effective bandwidth of your computation as a metric when measuring performance and optimization benefits.

8.2.1. Theoretical Bandwidth Calculation

Theoretical bandwidth can be calculated using hardware specifications available in the product literature. For example, the NVIDIA Tesla M2090 uses GDDR5 (double data rate) RAM with a memory clock rate of 1.85 GHz and a 384-bit-wide memory interface.

Using these data items, the peak theoretical memory bandwidth of the NVIDIA Tesla M2090 is 177.6 GB/s:

$$(1.85 \times 10^9 \times (384/8) \times 2) \div 10^9 = 177.6 \text{ GB/s}$$

In this calculation, the memory clock rate is converted in to Hz, multiplied by the interface width (divided by 8, to convert bits to bytes) and multiplied by 2 due to the double data rate. Finally, this product is divided by 10^9 to convert the result to GB/s.

Some calculations use 1024^3 instead of 10^9 for the final calculation. In such a case, the bandwidth would be 165.4GB/s. It is important to use the same divisor when calculating theoretical and effective bandwidth so that the comparison is valid.

When ECC is enabled, the effective maximum bandwidth is reduced by approximately 20% due to the additional traffic for the memory checksums, though the exact impact of ECC on bandwidth depends on the memory access pattern.

8.2.2. Effective Bandwidth Calculation

Effective bandwidth is calculated by timing specific program activities and by knowing how data is accessed by the program. To do so, use this equation:

$$\text{Effective bandwidth} = ((B_r + B_w) \div 10^9) \div \text{time}$$

Here, the effective bandwidth is in units of GB/s, B_r is the number of bytes read per kernel, B_w is the number of bytes written per kernel, and time is given in seconds.

For example, to compute the effective bandwidth of a 2048 x 2048 matrix copy, the following formula could be used:

$$\text{Effective bandwidth} = ((2048^2 \times 4 \times 2) \div 10^9) \div \text{time}$$

The number of elements is multiplied by the size of each element (4 bytes for a float), multiplied by 2 (because of the read *and* write), divided by 10^9 (or $1,024^3$) to obtain GB of memory transferred. This number is divided by the time in seconds to obtain GB/s.

8.2.3. Throughput Reported by Visual Profiler

For devices with [compute capability](#) of 2.0 or greater, the Visual Profiler can be used to collect several different memory throughput measures. The following throughput metrics can be displayed in the Details or Detail Graphs view:

- ▶ Requested Global Load Throughput
- ▶ Requested Global Store Throughput
- ▶ Global Load Throughput
- ▶ Global Store Throughput
- ▶ DRAM Read Throughput
- ▶ DRAM Write Throughput

The Requested Global Load Throughput and Requested Global Store Throughput values indicate the global memory throughput requested by the kernel and therefore correspond to the effective bandwidth obtained by the calculation shown under [Effective Bandwidth Calculation](#).

Because the minimum memory transaction size is larger than most word sizes, the actual memory throughput required for a kernel can include the transfer of data not used by the kernel. For global memory accesses, this actual throughput is reported by the Global Load Throughput and Global Store Throughput values.

It's important to note that both numbers are useful. The actual memory throughput shows how close the code is to the hardware limit, and a comparison of the effective or requested bandwidth to the actual bandwidth presents a good estimate of how much bandwidth is wasted by suboptimal coalescing of memory accesses (see [Coalesced Access to Global Memory](#)). For global memory accesses, this comparison of requested memory bandwidth to actual memory bandwidth is reported by the Global Memory Load Efficiency and Global Memory Store Efficiency metrics.

Note: the Visual Profiler uses 1024 when converting bytes/sec to GB/sec.

Chapter 9.

MEMORY OPTIMIZATIONS

Memory optimizations are the most important area for performance. The goal is to maximize the use of the hardware by maximizing bandwidth. Bandwidth is best served by using as much fast memory and as little slow-access memory as possible. This chapter discusses the various kinds of memory on the host and device and how best to set up data items to use the memory effectively.

9.1. Data Transfer Between Host and Device

The peak theoretical bandwidth between the device memory and the GPU is much higher (177.6 GB/s on the NVIDIA Tesla M2090, for example) than the peak theoretical bandwidth between host memory and device memory (8 GB/s on the PCIe x16 Gen2). Hence, for best overall application performance, it is important to minimize data transfer between the host and the device, even if that means running kernels on the GPU that do not demonstrate any speedup compared with running them on the host CPU.

High Priority: Minimize data transfer between the host and the device, even if it means running some kernels on the device that do not show performance gains when compared with running them on the host CPU.

Intermediate data structures should be created in device memory, operated on by the device, and destroyed without ever being mapped by the host or copied to host memory.

Also, because of the overhead associated with each transfer, batching many small transfers into one larger transfer performs significantly better than making each transfer separately, even if doing so requires packing non-contiguous regions of memory into a contiguous buffer and then unpacking after the transfer.

Finally, higher bandwidth between the host and the device is achieved when using *page-locked* (or *pinned*) memory, as discussed in the *CUDA C Programming Guide* and [Pinned Memory](#) of this document.

9.1.1. Pinned Memory

Page-locked or pinned memory transfers attain the highest bandwidth between the host and the device. On PCIe x16 Gen2 cards, for example, pinned memory can attain roughly 6GB/s transfer rates.

Pinned memory is allocated using the `cudaHostAlloc()` functions in the Runtime API. The `bandwidthTest` CUDA Sample shows how to use these functions as well as how to measure memory transfer performance.

For regions of system memory that have already been pre-allocated, `cudaHostRegister()` can be used to pin the memory on-the-fly without the need to allocate a separate buffer and copy the data into it.

Pinned memory should not be overused. Excessive use can reduce overall system performance because pinned memory is a scarce resource, but how much is too much is difficult to know in advance. Furthermore, the pinning of system memory is a heavyweight operation compared to most normal system memory allocations, so as with all optimizations, test the application and the systems it runs on for optimal performance parameters.

9.1.2. Asynchronous and Overlapping Transfers with Computation

Data transfers between the host and the device using `cudaMemcpy()` are blocking transfers; that is, control is returned to the host thread only after the data transfer is complete. The `cudaMemcpyAsync()` function is a non-blocking variant of `cudaMemcpy()` in which control is returned immediately to the host thread. In contrast with `cudaMemcpy()`, the asynchronous transfer version *requires* pinned host memory (see [Pinned Memory](#)), and it contains an additional argument, a stream ID. A *stream* is simply a sequence of operations that are performed in order on the device. Operations in different streams can be interleaved and in some cases overlapped - a property that can be used to hide data transfers between the host and the device.

Asynchronous transfers enable overlap of data transfers with computation in two different ways. On all CUDA-enabled devices, it is possible to overlap host computation with asynchronous data transfers and with device computations. For example, [Overlapping computation and data transfers](#) demonstrates how host computation in the routine `cpuFunction()` is performed while data is transferred to the device and a kernel using the device is executed.

Overlapping computation and data transfers

```
cudaMemcpyAsync(a_d, a_h, size, cudaMemcpyHostToDevice, 0);
kernel<<<grid, block>>>(a_d);
cpuFunction();
```

The last argument to the `cudaMemcpyAsync()` function is the stream ID, which in this case uses the default stream, stream 0. The kernel also uses the default stream, and

it will not begin execution until the memory copy completes; therefore, no explicit synchronization is needed. Because the memory copy and the kernel both return control to the host immediately, the host function `cpuFunction()` overlaps their execution.

In [Overlapping computation and data transfers](#), the memory copy and kernel execution occur sequentially. On devices that are capable of concurrent copy and compute, it is possible to overlap kernel execution on the device with data transfers between the host and the device. Whether a device has this capability is indicated by the `asyncEngineCount` field of the `cudaDeviceProp` structure (or listed in the output of the `deviceQuery` CUDA Sample). On devices that have this capability, the overlap once again requires pinned host memory, and, in addition, the data transfer and kernel must use different, non-default streams (streams with non-zero stream IDs). Non-default streams are required for this overlap because memory copy, memory set functions, and kernel calls that use the default stream begin only after all preceding calls on the device (in any stream) have completed, and no operation on the device (in any stream) commences until they are finished.

[Concurrent copy and execute](#) illustrates the basic technique.

Concurrent copy and execute

```
cudaStreamCreate(&stream1);
cudaStreamCreate(&stream2);
cudaMemcpyAsync(a_d, a_h, size, cudaMemcpyHostToDevice, stream1);
kernel<<<grid, block, 0, stream2>>>>(otherData_d);
```

In this code, two streams are created and used in the data transfer and kernel executions as specified in the last arguments of the `cudaMemcpyAsync` call and the kernel's execution configuration.

[Concurrent copy and execute](#) demonstrates how to overlap kernel execution with asynchronous data transfer. This technique could be used when the data dependency is such that the data can be broken into chunks and transferred in multiple stages, launching multiple kernels to operate on each chunk as it arrives. [Sequential copy and execute](#) and [Staged concurrent copy and execute](#) demonstrate this. They produce equivalent results. The first segment shows the reference sequential implementation, which transfers and operates on an array of N floats (where N is assumed to be evenly divisible by `nThreads`).

Sequential copy and execute

```
cudaMemcpy(a_d, a_h, N*sizeof(float), dir);
kernel<<<N/nThreads, nThreads>>>>(a_d);
```

[Staged concurrent copy and execute](#) shows how the transfer and kernel execution can be broken up into `nStreams` stages. This approach permits some overlapping of the data transfer and execution.

Staged concurrent copy and execute

```
size=N*sizeof(float)/nStreams;
for (i=0; i<nStreams; i++) {
    offset = i*N/nStreams;
```

```

    cudaMemcpyAsync(a_d+offset, a_h+offset, size, dir, stream[i]);
    kernel<<<N/(nThreads*nStreams), nThreads, 0,
              stream[i]>>>(a_d+offset);
}

```

(In **Staged concurrent copy and execute**, it is assumed that N is evenly divisible by $nThreads * nStreams$.) Because execution within a stream occurs sequentially, none of the kernels will launch until the data transfers in their respective streams complete. Current GPUs can simultaneously process asynchronous data transfers and execute kernels. GPUs with a single copy engine can perform one asynchronous data transfer and execute kernels whereas GPUs with two copy engines can simultaneously perform one asynchronous data transfer from the host to the device, one asynchronous data transfer from the device to the host, and execute kernels. The number of copy engines on a GPU is given by the `asyncEngineCount` field of the `cudaDeviceProp` structure, which is also listed in the output of the `deviceQuery` CUDA Sample. (It should be mentioned that it is not possible to overlap a blocking transfer with an asynchronous transfer, because the blocking transfer occurs in the default stream, so it will not begin until all previous CUDA calls complete. It will not allow any other CUDA call to begin until it has completed.) A diagram depicting the timeline of execution for the two code segments is shown in **Figure 1**, and `nStreams` is equal to 4 for **Staged concurrent copy and execute** in the bottom half of the figure.

Figure 1 Timeline comparison for copy and kernel execution

For this example, it is assumed that the data transfer and kernel execution times are comparable. In such cases, and when the execution time (t_E) exceeds the transfer time (t_T), a rough estimate for the overall time is $t_E + t_T/nStreams$ for the staged version versus $t_E + t_T$ for the sequential version. If the transfer time exceeds the execution time, a rough estimate for the overall time is $t_T + t_E/nStreams$.

9.1.3. Zero Copy

Zero copy is a feature that was added in version 2.2 of the CUDA Toolkit. It enables GPU threads to directly access host memory. For this purpose, it requires mapped pinned (non-pageable) memory. On integrated GPUs (i.e., GPUs with the integrated field of the CUDA device properties structure set to 1), mapped pinned memory is always a performance gain because it avoids superfluous copies as integrated GPU and CPU memory are physically the same. On discrete GPUs, mapped pinned memory is advantageous only in certain cases. Because the data is not cached on the GPU, mapped pinned memory should be read or written only once, and the global loads and stores that read and write the memory should be coalesced. Zero copy can be used in place of streams because kernel-originated data transfers automatically overlap kernel execution without the overhead of setting up and determining the optimal number of streams.

Low Priority: Use zero-copy operations on integrated GPUs for CUDA Toolkit version 2.2 and later.

The host code in [Zero-copy host code](#) shows how zero copy is typically set up.

Zero-copy host code

```
float *a_h, *a_map;
...
cudaGetDeviceProperties(&prop, 0);
if (!prop.canMapHostMemory)
    exit(0);
cudaSetDeviceFlags(cudaDeviceMapHost);
cudaHostAlloc(&a_h, nBytes, cudaHostAllocMapped);
cudaHostGetDevicePointer(&a_map, a_h, 0);
kernel<<<gridSize, blockSize>>>(a_map);
```

In this code, the **canMapHostMemory** field of the structure returned by **cudaGetDeviceProperties()** is used to check that the device supports mapping host memory to the device's address space. Page-locked memory mapping is enabled by calling **cudaSetDeviceFlags()** with **cudaDeviceMapHost**. Note that **cudaSetDeviceFlags()** must be called prior to setting a device or making a CUDA call that requires state (that is, essentially, before a context is created). Page-locked mapped host memory is allocated using **cudaHostAlloc()**, and the pointer to the mapped device address space is obtained via the function **cudaHostGetDevicePointer()**. In the code in [Zero-copy host code](#), **kernel()** can reference the mapped pinned host memory using the pointer **a_map** in exactly the same way as it would if **a_map** referred to a location in device memory.

Mapped pinned host memory allows you to overlap CPU-GPU memory transfers with computation while avoiding the use of CUDA streams. But since any repeated access to such memory areas causes repeated PCIe transfers, consider creating a second area in device memory to manually cache the previously read host memory data.

9.1.4. Unified Virtual Addressing

Devices of [compute capability 2.0](#) and later support a special addressing mode called *Unified Virtual Addressing* (UVA) on 64-bit Linux, Mac OS, and Windows XP and on Windows Vista/7 when using TCC driver mode. With UVA, the host memory and the device memories of all installed supported devices share a single virtual address space.

Prior to UVA, an application had to keep track of which pointers referred to device memory (and for which device) and which referred to host memory as a separate bit of metadata (or as hard-coded information in the program) for each pointer. Using UVA, on the other hand, the physical memory space to which a pointer points can be determined simply by inspecting the value of the pointer using `cudaPointerGetAttributes()`.

Under UVA, pinned host memory allocated with `cudaHostAlloc()` will have identical host and device pointers, so it is not necessary to call `cudaHostGetDevicePointer()` for such allocations. Host memory allocations pinned after-the-fact via `cudaHostRegister()`, however, will continue to have different device pointers than their host pointers, so `cudaHostGetDevicePointer()` remains necessary in that case.

UVA is also a necessary precondition for enabling peer-to-peer (P2P) transfer of data directly across the PCIe bus for supported GPUs in supported configurations, bypassing host memory.

See the *CUDA C Programming Guide* for further explanations and software requirements for UVA and P2P.

9.2. Device Memory Spaces

CUDA devices use several memory spaces, which have different characteristics that reflect their distinct usages in CUDA applications. These memory spaces include global, local, shared, texture, and registers, as shown in [Figure 2](#).

Figure 2 Memory spaces on a CUDA device

Of these different memory spaces, global memory is the most plentiful; see *Features and Technical Specifications* of the *CUDA C Programming Guide* for the amounts of memory available in each memory space at each [compute capability](#) level. Global, local, and texture memory have the greatest access latency, followed by constant memory, shared memory, and the register file.

The various principal traits of the memory types are shown in [Table 1](#).

Table 1 Salient Features of Device Memory

Memory	Location on/off chip	Cached	Access	Scope	Lifetime
Register	On	n/a	R/W	1 thread	Thread
Local	Off	†	R/W	1 thread	Thread
Shared	On	n/a	R/W	All threads in block	Block
Global	Off	†	R/W	All threads + host	Host allocation
Constant	Off	Yes	R	All threads + host	Host allocation
Texture	Off	Yes	R	All threads + host	Host allocation

† Cached only on devices of compute capability 2.x.

In the case of texture access, if a texture reference is bound to a linear array in global memory, then the device code can write to the underlying array. Texture references that are bound to CUDA arrays can be written to via surface-write operations by binding a surface to the same underlying CUDA array storage). Reading from a texture while

writing to its underlying global memory array in the same kernel launch should be avoided because the texture caches are read-only and are not invalidated when the associated global memory is modified.

9.2.1. Coalesced Access to Global Memory

Perhaps the single most important performance consideration in programming for CUDA-capable GPU architectures is the coalescing of global memory accesses. Global memory loads and stores by threads of a warp (of a half warp for devices of [compute capability](#) 1.x) are coalesced by the device into as few as one transaction when certain access requirements are met.

High Priority: Ensure global memory accesses are coalesced whenever possible.

The access requirements for coalescing depend on the compute capability of the device and are documented in the *CUDA C Programming Guide*.

For devices of compute capability 2.x, the requirements can be summarized quite easily: the concurrent accesses of the threads of a warp will coalesce into a number of transactions equal to the number of cache lines necessary to service all of the threads of the warp. By default, all accesses are cached through L1, which has 128-byte lines. For scattered access patterns, to reduce overfetch, it can sometimes be useful to cache only in L2, which caches shorter 32-byte segments (see the *CUDA C Programming Guide*).

For devices of compute capability 3.0 and 3.5, accesses to global memory are cached only in L2; L1 is reserved for local memory accesses.

Accessing memory in a coalesced way is even more important when ECC is turned on. Scattered accesses increase ECC memory transfer overhead, especially when writing data to the global memory.

Coalescing concepts are illustrated in the following simple examples. These examples assume compute capability 2.x. These examples assume that accesses are cached through L1, which is the default behavior on those devices, and that accesses are for 4-byte words, unless otherwise noted.

9.2.1.1. A Simple Access Pattern

The first and simplest case of coalescing can be achieved by any CUDA-enabled device: the k -th thread accesses the k -th word in a cache line. Not all threads need to participate.

For example, if the threads of a warp access adjacent 4-byte words (e.g., adjacent `float` values), a single 128B L1 cache line and therefore a single coalesced transaction will service that memory access. Such a pattern is shown in [Figure 3](#).

Figure 3 Coalesced access - all threads access one cache line

This access pattern results in a single 128-byte L1 transaction, indicated by the red rectangle.

If some words of the line had not been requested by any thread (such as if several threads had accessed the same word or if some threads did not participate in the access), all data in the cache line is fetched anyway. Furthermore, if accesses by the threads of the warp had been permuted within this segment, still only one 128-byte L1 transaction would have been performed by a device with [compute capability 2.x](#).

9.2.1.2. A Sequential but Misaligned Access Pattern

If sequential threads in a warp access memory that is sequential but not aligned with the cache lines, two 128-byte L1 cache will be requested, as shown in [Figure 4](#).

Figure 4 Unaligned sequential addresses that fit into two 128-byte L1-cache lines

For non-caching transactions (i.e., those that bypass L1 and use only the L2 cache), a similar effect is seen, except at the level of the 32-byte L2 segments. In [Figure 5](#), we see an example of this: the same access pattern from [Figure 4](#) is used, but now L1 caching is disabled, so now five 32-byte L2 segments are needed to satisfy the request.

Figure 5 Misaligned sequential addresses that fall within five 32-byte L2-cache segments

Memory allocated through the CUDA Runtime API, such as via `cudaMalloc()`, is guaranteed to be aligned to at least 256 bytes. Therefore, choosing sensible thread block sizes, such as multiples of the warp size (i.e., 32 on current GPUs), facilitates memory

accesses by warps that are aligned to cache lines. (Consider what would happen to the memory addresses accessed by the second, third, and subsequent thread blocks if the thread block size was not a multiple of warp size, for example.)

9.2.1.3. Effects of Misaligned Accesses

It is easy and informative to explore the ramifications of misaligned accesses using a simple copy kernel, such as the one in [A copy kernel that illustrates misaligned accesses](#).

A copy kernel that illustrates misaligned accesses

```
__global__ void offsetCopy(float *odata, float* idata, int offset)
{
    int xid = blockIdx.x * blockDim.x + threadIdx.x + offset;
    odata[xid] = idata[xid];
}
```

In [A copy kernel that illustrates misaligned accesses](#), data is copied from the input array `idata` to the output array, both of which exist in global memory. The kernel is executed within a loop in host code that varies the parameter `offset` from 0 to 32. (Figure 4 and Figure 4 correspond to misalignments in the cases of caching and non-caching memory accesses, respectively.) The effective bandwidth for the copy with various offsets on an NVIDIA Tesla M2090 (compute capability 2.0, with ECC turned on, as it is by default) is shown in Figure 6.

Figure 6 Performance of offsetCopy kernel

For the NVIDIA Tesla M2090, global memory accesses with no offset or with offsets that are multiples of 32 words result in a single L1 cache line transaction or 4 L2 cache

segment loads (for non-L1-caching loads). The achieved bandwidth is approximately 130GB/s. Otherwise, either two L1 cache lines (caching mode) or four to five L2 cache segments (non-caching mode) are loaded per warp, resulting in approximately $4/5^{\text{th}}$ of the memory throughput achieved with no offsets.

An interesting point is that we might expect the caching case to perform worse than the non-caching case for this sample, given that each warp in the caching case fetches twice as many bytes as it requires, whereas in the non-caching case, only $5/4$ as many bytes as required are fetched per warp. In this particular example, that effect is not apparent, however, because adjacent warps reuse the cache lines their neighbors fetched. So while the impact is still evident in the case of caching loads, it is not as great as we might have expected. It would have been more so if adjacent warps had not exhibited such a high degree of reuse of the over-fetched cache lines.

9.2.1.4. Strided Accesses

As seen above, in the case of misaligned sequential accesses, the caches of **compute capability** 2.x devices help a lot to achieve reasonable performance. It may be different with non-unit-strided accesses, however, and this is a pattern that occurs frequently when dealing with multidimensional data or matrices. For this reason, ensuring that as much as possible of the data in each cache line fetched is actually used is an important part of performance optimization of memory accesses on these devices.

To illustrate the effect of strided access on effective bandwidth, see the kernel **strideCopy()** in [A kernel to illustrate non-unit stride data copy](#), which copies data with a stride of stride elements between threads from **idata** to **odata**.

A kernel to illustrate non-unit stride data copy

```
__global__ void strideCopy(float *odata, float* idata, int stride)
{
    int xid = (blockIdx.x*blockDim.x + threadIdx.x)*stride;
    odata[xid] = idata[xid];
}
```

[Figure 7](#) illustrates such a situation; in this case, threads within a warp access words in memory with a stride of 2. This action leads to a load of two L1 cache lines (or eight L2 cache segments in non-caching mode) per warp on the Tesla M2090 (compute capability 2.0).

Figure 7 Adjacent threads accessing memory with a stride of 2

A stride of 2 results in a 50% of load/store efficiency since half the elements in the transaction are not used and represent wasted bandwidth. As the stride increases, the effective bandwidth decreases until the point where 32 lines of cache are loaded for the 32 threads in a warp, as indicated in Figure 8.

Figure 8 Performance of strideCopy kernel

As illustrated in [Figure 8](#), non-unit-stride global memory accesses should be avoided whenever possible. One method for doing so utilizes shared memory, which is discussed in the next section.

9.2.2. Shared Memory

Because it is on-chip, shared memory has much higher bandwidth and lower latency than local and global memory - provided there are no bank conflicts between the threads, as detailed in the following section.

9.2.2.1. Shared Memory and Memory Banks

To achieve high memory bandwidth for concurrent accesses, shared memory is divided into equally sized memory modules (*banks*) that can be accessed simultaneously. Therefore, any memory load or store of n addresses that spans n distinct memory banks can be serviced simultaneously, yielding an effective bandwidth that is n times as high as the bandwidth of a single bank.

However, if multiple addresses of a memory request map to the same memory bank, the accesses are serialized. The hardware splits a memory request that has bank conflicts into as many separate conflict-free requests as necessary, decreasing the effective bandwidth by a factor equal to the number of separate memory requests. The one exception here is when multiple threads in a warp address the same shared memory location, resulting in a broadcast. Devices of [compute capability 1.x](#) require all threads of a half-warp to access the same address in shared memory for broadcast to occur; devices of compute capability 2.x and higher have the additional ability to multicast shared memory accesses (i.e. to send copies of the same value to several threads of the warp).

To minimize bank conflicts, it is important to understand how memory addresses map to memory banks and how to optimally schedule memory requests.

Compute Capability 1.x

On devices of compute capability 1.x, each bank has a bandwidth of 32 bits every two clock cycles, and successive 32-bit words are assigned to successive banks. The warp size is 32 threads and the number of banks is 16, so a shared memory request for a warp is split into one request for the first half of the warp and one request for the second half of the warp. No bank conflict occurs if only one memory location per bank is accessed by a half warp of threads.

Compute Capability 2.x

On devices of compute capability 2.x, each bank has a bandwidth of 32 bits every two clock cycles, and successive 32-bit words are assigned to successive banks. The warp size is 32 threads and the number of banks is also 32, so bank conflicts can occur between any threads in the warp. See *Compute Capability 2.x* in the *CUDA C Programming Guide* for further details.

Compute Capability 3.x

On devices of compute capability 3.x, each bank has a bandwidth of 64 bits every clock cycle (*). There are two different banking modes: either successive 32-bit words (in 32-bit mode) or successive 64-bit words (64-bit mode) are assigned to successive banks. The warp size is 32 threads and the number of banks is also 32, so bank conflicts can occur between any threads in the warp. See *Compute Capability 3.x* in the *CUDA C Programming Guide* for further details.

(*) However, devices of compute capability 3.x typically have lower clock frequencies than devices of compute capability 1.x or 2.x for improved power efficiency.

9.2.2.2. Shared Memory in Matrix Multiplication ($C=AB$)

Shared memory enables cooperation between threads in a block. When multiple threads in a block use the same data from global memory, shared memory can be used to access the data from global memory only once. Shared memory can also be used to avoid uncoalesced memory accesses by loading and storing data in a coalesced pattern from global memory and then reordering it in shared memory. Aside from memory bank conflicts, there is no penalty for non-sequential or unaligned accesses by a warp in shared memory.

The use of shared memory is illustrated via the simple example of a matrix multiplication $C = AB$ for the case with A of dimension $M \times w$, B of dimension $w \times N$, and C of dimension $M \times N$. To keep the kernels simple, M and N are multiples of 32, and w is 16 for devices of compute capability 1.x or 32 for devices of **compute capability 2.0** or higher.

A natural decomposition of the problem is to use a block and tile size of $w \times w$ threads. Therefore, in terms of $w \times w$ tiles, A is a column matrix, B is a row matrix, and C is their outer product; see **Figure 9**. A grid of N/w by M/w blocks is launched, where each thread block calculates the elements of a different tile in C from a single tile of A and a single tile of B .

Figure 9 Block-column matrix multiplied by block-row matrix
Block-column matrix (A) multiplied by block-row matrix (B) with resulting product matrix (C).

To do this, the **simpleMultiply** kernel ([Unoptimized matrix multiplication](#)) calculates the output elements of a tile of matrix C.

Unoptimized matrix multiplication

```
__global__ void simpleMultiply(float *a, float* b, float *c,
                              int N)
{
    int row = blockIdx.y * blockDim.y + threadIdx.y;
    int col = blockIdx.x * blockDim.x + threadIdx.x;
    float sum = 0.0f;
    for (int i = 0; i < TILE_DIM; i++) {
        sum += a[row*TILE_DIM+i] * b[i*N+col];
    }
    c[row*N+col] = sum;
}
```

In [Unoptimized matrix multiplication](#), **a**, **b**, and **c** are pointers to global memory for the matrices A, B, and C, respectively; **blockDim.x**, **blockDim.y**, and **TILE_DIM** are all equal to **w**. Each thread in the **w****x****w**-thread block calculates one element in a tile of C. **row** and **col** are the row and column of the element in C being calculated by a particular thread. The **for** loop over **i** multiplies a row of A by a column of B, which is then written to C.

The effective bandwidth of this kernel is only 6.6GB/s on an NVIDIA Tesla K20X (with ECC off). To analyze performance, it is necessary to consider how warps access global memory in the **for** loop. Each warp of threads calculates one row of a tile of C, which depends on a single row of A and an entire tile of B as illustrated in [Figure 10](#).

Figure 10 Computing a row of a tile
Computing a row of a tile in C using one row of A and an entire tile of B.

For each iteration i of the `for` loop, the threads in a warp read a row of the B tile, which is a sequential and coalesced access for all compute capabilities.

However, for each iteration i , all threads in a warp read the same value from global memory for matrix A, as the index `row*TILE_DIM+i` is constant within a warp. Even though such an access requires only 1 transaction on devices of compute capability 2.0 or higher, there is wasted bandwidth in the transaction, because only one 4-byte word out of 32 words in the cache line is used. We can reuse this cache line in subsequent iterations of the loop, and we would eventually utilize all 32 words; however, when many warps execute on the same multiprocessor simultaneously, as is generally the case, the cache line may easily be evicted from the cache between iterations i and $i+1$.

The performance on a device of any compute capability can be improved by reading a tile of A into shared memory as shown in [Using shared memory to improve the global memory load efficiency in matrix multiplication](#).

Using shared memory to improve the global memory load efficiency in matrix multiplication

```
__global__ void coalescedMultiply(float *a, float* b, float *c,
                                int N)
{
    __shared__ float aTile[TILE_DIM][TILE_DIM];

    int row = blockIdx.y * blockDim.y + threadIdx.y;
    int col = blockIdx.x * blockDim.x + threadIdx.x;
    float sum = 0.0f;
    aTile[threadIdx.y][threadIdx.x] = a[row*TILE_DIM+threadIdx.x];
    for (int i = 0; i < TILE_DIM; i++) {
        sum += aTile[threadIdx.y][i] * b[i*N+col];
    }
    c[row*N+col] = sum;
}
```

In [Using shared memory to improve the global memory load efficiency in matrix multiplication](#), each element in a tile of A is read from global memory only once, in a fully coalesced fashion (with no wasted bandwidth), to shared memory. Within each iteration of the **for** loop, a value in shared memory is broadcast to all threads in a warp. No **__syncthreads()** synchronization barrier call is needed after reading the tile of A into shared memory because only threads within the warp that write the data into shared memory read the data (Note: in lieu of **__syncthreads()**, the **__shared__ array** may need to be marked as **volatile** for correctness on devices of compute capability 2.0 or higher; see the *NVIDIA Fermi Compatibility Guide*). This kernel has an effective bandwidth of 7.8GB/s on an NVIDIA Tesla K20X. This illustrates the use of the shared memory as a *user-managed cache* when the hardware L1 cache eviction policy does not match up well with the needs of the application or when L1 cache is not used for reads from global memory.

A further improvement can be made to how [Using shared memory to improve the global memory load efficiency in matrix multiplication](#) deals with matrix B. In calculating each of the rows of a tile of matrix C, the entire tile of B is read. The repeated reading of the B tile can be eliminated by reading it into shared memory once ([Improvement by reading additional data into shared memory](#)).

Improvement by reading additional data into shared memory

```
__global__ void sharedABMultiply(float *a, float* b, float *c,
                                int N)
{
    __shared__ float aTile[TILE_DIM][TILE_DIM],
                    bTile[TILE_DIM][TILE_DIM];
    int row = blockIdx.y * blockDim.y + threadIdx.y;
    int col = blockIdx.x * blockDim.x + threadIdx.x;
    float sum = 0.0f;
    aTile[threadIdx.y][threadIdx.x] = a[row*TILE_DIM+threadIdx.x];
    bTile[threadIdx.y][threadIdx.x] = b[threadIdx.y*N+col];
    __syncthreads();
    for (int i = 0; i < TILE_DIM; i++) {
        sum += aTile[threadIdx.y][i] * bTile[i][threadIdx.x];
    }
    c[row*N+col] = sum;
}
```

Note that in [Improvement by reading additional data into shared memory](#), a **__syncthreads()** call is required after reading the B tile because a warp reads data from shared memory that were written to shared memory by different warps. The effective bandwidth of this routine is 14.9 GB/s on an NVIDIA Tesla K20X. Note that the performance improvement is not due to improved coalescing in either case, but to avoiding redundant transfers from global memory.

The results of the various optimizations are summarized in [Table 2](#).

Table 2 Performance Improvements Optimizing C = AB Matrix Multiply

Optimization	NVIDIA Tesla K20X
No optimization	6.6 GB/s

Optimization	NVIDIA Tesla K20X
Coalesced using shared memory to store a tile of A	7.8 GB/s
Using shared memory to eliminate redundant reads of a tile of B	14.9 GB/s

Medium Priority: Use shared memory to avoid redundant transfers from global memory.

9.2.2.3. Shared Memory in Matrix Multiplication ($C=AA^T$)

A variant of the previous matrix multiplication can be used to illustrate how strided accesses to global memory, as well as shared memory bank conflicts, are handled. This variant simply uses the transpose of A in place of B, so $C = AA^T$.

A simple implementation for $C = AA^T$ is shown in [Unoptimized handling of strided accesses to global memory](#)

Unoptimized handling of strided accesses to global memory

```
__global__ void simpleMultiply(float *a, float *c, int M)
{
    int row = blockIdx.y * blockDim.y + threadIdx.y;
    int col = blockIdx.x * blockDim.x + threadIdx.x;
    float sum = 0.0f;
    for (int i = 0; i < TILE_DIM; i++) {
        sum += a[row*TILE_DIM+i] * a[col*TILE_DIM+i];
    }
    c[row*M+col] = sum;
}
```

In [Unoptimized handling of strided accesses to global memory](#), the *row*-th, *col*-th element of C is obtained by taking the dot product of the *row*-th and *col*-th rows of A. The effective bandwidth for this kernel is 3.64 GB/s on an NVIDIA Tesla M2090. These results are substantially lower than the corresponding measurements for the $C = AB$ kernel. The difference is in how threads in a half warp access elements of A in the second term, `a[col*TILE_DIM+i]`, for each iteration *i*. For a warp of threads, `col` represents sequential columns of the transpose of A, and therefore `col*TILE_DIM` represents a strided access of global memory with a stride of *w*, resulting in plenty of wasted bandwidth.

The way to avoid strided access is to use shared memory as before, except in this case a warp reads a row of A into a column of a shared memory tile, as shown in [An optimized handling of strided accesses using coalesced reads from global memory](#).

An optimized handling of strided accesses using coalesced reads from global memory

```
__global__ void coalescedMultiply(float *a, float *c, int M)
{
    __shared__ float aTile[TILE_DIM][TILE_DIM],
        transposedTile[TILE_DIM][TILE_DIM];
```

```

int row = blockIdx.y * blockDim.y + threadIdx.y;
int col = blockIdx.x * blockDim.x + threadIdx.x;
float sum = 0.0f;
aTile[threadIdx.y][threadIdx.x] = a[row*TILE_DIM+threadIdx.x];
transposedTile[threadIdx.x][threadIdx.y] =
    a[(blockIdx.x*blockDim.x + threadIdx.y)*TILE_DIM +
      threadIdx.x];
__syncthreads();
for (int i = 0; i < TILE_DIM; i++) {
    sum += aTile[threadIdx.y][i] * transposedTile[i][threadIdx.x];
}
c[row*M+col] = sum;
}

```

An optimized handling of strided accesses using coalesced reads from global memory uses the shared **transposedTile** to avoid uncoalesced accesses in the second term in the dot product and the shared **aTile** technique from the previous example to avoid uncoalesced accesses in the first term. The effective bandwidth of this kernel is 27.5 GB/s on an NVIDIA Tesla M2090. These results are slightly lower than those obtained by the final kernel for $C = AB$. The cause of the difference is shared memory bank conflicts.

The reads of elements in **transposedTile** within the for loop are free of conflicts, because threads of each half warp read across rows of the tile, resulting in unit stride across the banks. However, bank conflicts occur when copying the tile from global memory into shared memory. To enable the loads from global memory to be coalesced, data are read from global memory sequentially. However, this requires writing to shared memory in columns, and because of the use of $w \times w$ tiles in shared memory, this results in a stride between threads of w banks - every thread of the warp hits the same bank. (Recall that w is selected as 16 for devices of **compute capability** 1.x and 32 for devices of compute capability 2.0 or higher.) These many-way bank conflicts are very expensive. The simple remedy is to pad the shared memory array so that it has an extra column, as in the following line of code.

```
__shared__ float transposedTile[TILE_DIM][TILE_DIM+1];
```

This padding eliminates the conflicts entirely, because now the stride between threads is $w+1$ banks (i.e., 17 or 33, depending on the compute capability), which, due to modulo arithmetic used to compute bank indices, is equivalent to a unit stride. After this change, the effective bandwidth is 39.2 GB/s on an NVIDIA Tesla M2090, which is comparable to the results from the last $C = AB$ kernel.

The results of these optimizations are summarized in [Table 3](#).

Table 3 Performance Improvements Optimizing $C = AA^T$ Matrix Multiplication

Optimization	NVIDIA Tesla M2090
No optimization	3.6 GB/s
Using shared memory to coalesce global reads	27.5 GB/s
Removing bank conflicts	39.2 GB/s

These results should be compared with those in [Table 2](#). As can be seen from these tables, judicious use of shared memory can dramatically improve performance.

The examples in this section have illustrated three reasons to use shared memory:

- ▶ To enable coalesced accesses to global memory, especially to avoid large strides (for general matrices, strides are much larger than 32)
- ▶ To eliminate (or reduce) redundant loads from global memory
- ▶ To avoid wasted bandwidth

9.2.3. Local Memory

Local memory is so named because its scope is local to the thread, not because of its physical location. In fact, local memory is off-chip. Hence, access to local memory is as expensive as access to global memory. Like global memory, local memory is not cached on devices of [compute capability](#) 1.x. In other words, the term *local* in the name does not imply faster access.

Local memory is used only to hold automatic variables. This is done by the **nvcc** compiler when it determines that there is insufficient register space to hold the variable. Automatic variables that are likely to be placed in local memory are large structures or arrays that would consume too much register space and arrays that the compiler determines may be indexed dynamically.

Inspection of the PTX assembly code (obtained by compiling with **-ptx** or **-keep** command-line options to **nvcc**) reveals whether a variable has been placed in local memory during the first compilation phases. If it has, it will be declared using the **.local** mnemonic and accessed using the **ld.local** and **st.local** mnemonics. If it has not, subsequent compilation phases might still decide otherwise, if they find the variable consumes too much register space for the targeted architecture. There is no way to check this for a specific variable, but the compiler reports total local memory usage per kernel (**lmem**) when run with the **--ptxas-options=-v** option.

9.2.4. Texture Memory

The read-only texture memory space is cached. Therefore, a texture fetch costs one device memory read only on a cache miss; otherwise, it just costs one read from the texture cache. The texture cache is optimized for 2D spatial locality, so threads of the same warp that read texture addresses that are close together will achieve best performance. Texture memory is also designed for streaming fetches with a constant latency; that is, a cache hit reduces DRAM bandwidth demand, but not fetch latency.

In certain addressing situations, reading device memory through texture fetching can be an advantageous alternative to reading device memory from global or constant memory.

9.2.4.1. Additional Texture Capabilities

If textures are fetched using **tex1D()**, **tex2D()**, or **tex3D()** rather than **tex1Dfetch()**, the hardware provides other capabilities that might be useful for some applications such as image processing, as shown in [Table 4](#).

Table 4 Useful Features for tex1D(), tex2D(), and tex3D() Fetches

Feature	Use	Caveat
Filtering	Fast, low-precision interpolation between texels	Valid only if the texture reference returns floating-point data
Normalized texture coordinates	Resolution-independent coding	None
Addressing modes	Automatic handling of boundary cases ¹	Can be used only with normalized texture coordinates
¹ The automatic handling of boundary cases in the bottom row of Table 4 refers to how a texture coordinate is resolved when it falls outside the valid addressing range. There are two options: <i>clamp</i> and <i>wrap</i> . If x is the coordinate and N is the number of texels for a one-dimensional texture, then with <i>clamp</i> , x is replaced by 0 if $x < 0$ and by $1-1/N$ if $1 \leq x$. With <i>wrap</i> , x is replaced by $\text{frac}(x)$ where $\text{frac}(x) = x - \text{floor}(x)$. Floor returns the largest integer less than or equal to x . So, in clamp mode where $N = 1$, an x of 1.3 is clamped to 1.0; whereas in wrap mode, it is converted to 0.3		

Within a kernel call, the texture cache is not kept coherent with respect to global memory writes, so texture fetches from addresses that have been written via global stores in the same kernel call return undefined data. That is, a thread can safely read a memory location via texture if the location has been updated by a previous kernel call or memory copy, but not if it has been previously updated by the same thread or another thread within the same kernel call.

9.2.5. Constant Memory

There is a total of 64 KB constant memory on a device. The constant memory space is cached. As a result, a read from constant memory costs one memory read from device memory only on a cache miss; otherwise, it just costs one read from the constant cache. Accesses to different addresses by threads within a warp are serialized, thus the cost scales linearly with the number of unique addresses read by all threads within a warp. As such the constant cache is best when threads in the same warp access only a few distinct locations. If all threads access the same location then constant memory can be as fast as a register.

9.2.6. Registers

Generally, accessing a register consumes zero extra clock cycles per instruction, but delays may occur due to register read-after-write dependencies and register memory bank conflicts.

The latency of read-after-write dependencies is approximately 24 cycles, but this latency is completely hidden on multiprocessors that have at least 192 active threads (that is, 6 warps) for devices of [compute capability 1.x](#) (8 CUDA cores per multiprocessor * 24 cycles of latency = 192 active threads to cover that latency). For devices of compute capability 2.0, which have 32 CUDA cores per multiprocessor, as many as 768 threads might be required to completely hide latency, and so on for devices of higher compute capabilities.

The compiler and hardware thread scheduler will schedule instructions as optimally as possible to avoid register memory bank conflicts. They achieve the best results when

the number of threads per block is a multiple of 64. Other than following this rule, an application has no direct control over these bank conflicts. In particular, there is no register-related reason to pack data into **float4** or **int4** types.

9.2.6.1. Register Pressure

Register pressure occurs when there are not enough registers available for a given task. Even though each multiprocessor contains thousands of 32-bit registers (see *Features and Technical Specifications* of the *CUDA C Programming Guide*), these are partitioned among concurrent threads. To prevent the compiler from allocating too many registers, use the **-maxrregcount=N** compiler command-line option (see [nvcc](#)) or the launch bounds kernel definition qualifier (see *Execution Configuration* of the *CUDA C Programming Guide*) to control the maximum number of registers to allocated per thread.

9.3. Allocation

Device memory allocation and de-allocation via **cudaMalloc()** and **cudaFree()** are expensive operations, so device memory should be reused and/or sub-allocated by the application wherever possible to minimize the impact of allocations on overall performance.

Chapter 10.

EXECUTION CONFIGURATION OPTIMIZATIONS

One of the keys to good performance is to keep the multiprocessors on the device as busy as possible. A device in which work is poorly balanced across the multiprocessors will deliver suboptimal performance. Hence, it's important to design your application to use threads and blocks in a way that maximizes hardware utilization and to limit practices that impede the free distribution of work. A key concept in this effort is occupancy, which is explained in the following sections.

Hardware utilization can also be improved in some cases by designing your application so that multiple, independent kernels can execute at the same time. Multiple kernels executing at the same time is known as concurrent kernel execution. Concurrent kernel execution is described below.

Another important concept is the management of system resources allocated for a particular task. How to manage this resource utilization is discussed in the final sections of this chapter.

10.1. Occupancy

Thread instructions are executed sequentially in CUDA, and, as a result, executing other warps when one warp is paused or stalled is the only way to hide latencies and keep the hardware busy. Some metric related to the number of active warps on a multiprocessor is therefore important in determining how effectively the hardware is kept busy. This metric is *occupancy*.

Occupancy is the ratio of the number of active warps per multiprocessor to the maximum number of possible active warps. (To determine the latter number, see the **deviceQuery** CUDA Sample or refer to *Compute Capabilities* in the *CUDA C Programming Guide*.) Another way to view occupancy is the percentage of the hardware's ability to process warps that is actively in use.

Higher occupancy does not always equate to higher performance—there is a point above which additional occupancy does not improve performance. However, low occupancy

always interferes with the ability to hide memory latency, resulting in performance degradation.

10.1.1. Calculating Occupancy

One of several factors that determine occupancy is register availability. Register storage enables threads to keep local variables nearby for low-latency access. However, the set of registers (known as the *register file*) is a limited commodity that all threads resident on a multiprocessor must share. Registers are allocated to an entire block all at once. So, if each thread block uses many registers, the number of thread blocks that can be resident on a multiprocessor is reduced, thereby lowering the occupancy of the multiprocessor. The maximum number of registers per thread can be set manually at compilation time per-file using the `-maxrregcount` option or per-kernel using the `__launch_bounds__` qualifier (see [Register Pressure](#)).

For purposes of calculating occupancy, the number of registers used by each thread is one of the key factors. For example, devices with [compute capability](#) 1.0 and 1.1 have 8,192 32-bit registers per multiprocessor and can have a maximum of 768 simultaneous threads resident (24 warps x 32 threads per warp). This means that in one of these devices, for a multiprocessor to have 100% occupancy, each thread can use at most 10 registers. However, this approach of determining how register count affects occupancy does not take into account the register allocation granularity. For example, on a device of compute capability 1.0, a kernel with 128-thread blocks using 12 registers per thread results in an occupancy of 83% with 5 active 128-thread blocks per multiprocessor, whereas a kernel with 256-thread blocks using the same 12 registers per thread results in an occupancy of 66% because only two 256-thread blocks can reside on a multiprocessor. Furthermore, register allocations are rounded up to the nearest 256 registers per block on devices with compute capability 1.0 and 1.1.

The number of registers available, the maximum number of simultaneous threads resident on each multiprocessor, and the register allocation granularity vary over different compute capabilities. Because of these nuances in register allocation and the fact that a multiprocessor's shared memory is also partitioned between resident thread blocks, the exact relationship between register usage and occupancy can be difficult to determine. The `--ptxas options=v` option of `nvcc` details the number of registers used per thread for each kernel. See *Hardware Multithreading* of the *CUDA C Programming Guide* for the register allocation formulas for devices of various compute capabilities and *Features and Technical Specifications* of the *CUDA C Programming Guide* for the total number of registers available on those devices. Alternatively, NVIDIA provides an occupancy calculator in the form of an Excel spreadsheet that enables developers to hone in on the optimal balance and to test different possible scenarios more easily. This spreadsheet, shown in [Figure 11](#), is called `CUDA_Occupancy_Calculator.xls` and is located in the `tools` subdirectory of the CUDA Toolkit installation.

Figure 11 Using the CUDA Occupancy Calculator to project GPU multiprocessor occupancy

In addition to the calculator spreadsheet, occupancy can be determined using the NVIDIA Visual Profiler's Achieved Occupancy metric. The Visual Profiler also calculates occupancy as part of the Multiprocessor stage of application analysis.

10.2. Concurrent Kernel Execution

As described in [Asynchronous and Overlapping Transfers with Computation](#), CUDA streams can be used to overlap kernel execution with data transfers. On devices that are capable of concurrent kernel execution, streams can also be used to execute multiple kernels simultaneously to more fully take advantage of the device's multiprocessors. Whether a device has this capability is indicated by the `concurrentKernels` field of the `cudaDeviceProp` structure (or listed in the output of the `deviceQuery` CUDA Sample). Non-default streams (streams other than stream 0) are required for concurrent execution because kernel calls that use the default stream begin only after all preceding calls on the device (in any stream) have completed, and no operation on the device (in any stream) commences until they are finished.

The following example illustrates the basic technique. Because `kernel1` and `kernel2` are executed in different, non-default streams, a capable device can execute the kernels at the same time.

```
cudaStreamCreate(&stream1);
cudaStreamCreate(&stream2);
```

```
kernel1<<<grid, block, 0, stream1>>>(data_1);
kernel2<<<grid, block, 0, stream2>>>(data_2);
```

10.3. Hiding Register Dependencies

Medium Priority: To hide latency arising from register dependencies, maintain sufficient numbers of active threads per multiprocessor (i.e., sufficient occupancy).

Register dependencies arise when an instruction uses a result stored in a register written by an instruction before it. The latency on current CUDA-enabled GPUs is approximately 24 cycles, so threads must wait 24 cycles before using an arithmetic result. However, this latency can be completely hidden by the execution of threads in other warps. See [Registers](#) for details.

10.4. Thread and Block Heuristics

Medium Priority: The number of threads per block should be a multiple of 32 threads, because this provides optimal computing efficiency and facilitates coalescing.

The dimension and size of blocks per grid and the dimension and size of threads per block are both important factors. The multidimensional aspect of these parameters allows easier mapping of multidimensional problems to CUDA and does not play a role in performance. As a result, this section discusses size but not dimension.

Latency hiding and occupancy depend on the number of active warps per multiprocessor, which is implicitly determined by the execution parameters along with resource (register and shared memory) constraints. Choosing execution parameters is a matter of striking a balance between latency hiding (occupancy) and resource utilization.

Choosing the execution configuration parameters should be done in tandem; however, there are certain heuristics that apply to each parameter individually. When choosing the first execution configuration parameter-the number of blocks per grid, or *grid size* - the primary concern is keeping the entire GPU busy. The number of blocks in a grid should be larger than the number of multiprocessors so that all multiprocessors have at least one block to execute. Furthermore, there should be multiple active blocks per multiprocessor so that blocks that aren't waiting for a `__syncthreads()` can keep the hardware busy. This recommendation is subject to resource availability; therefore, it should be determined in the context of the second execution parameter - the number of threads per block, or *block size* - as well as shared memory usage. To scale to future devices, the number of blocks per kernel launch should be in the thousands.

When choosing the block size, it is important to remember that multiple concurrent blocks can reside on a multiprocessor, so occupancy is not determined by block size alone. In particular, a larger block size does not imply a higher occupancy. For example, on a device of compute capability 1.1 or lower, a kernel with a maximum block size of 512 threads results in an occupancy of 66 percent because the maximum number of

threads per multiprocessor on such a device is 768. Hence, only a single block can be active per multiprocessor. However, a kernel with 256 threads per block on such a device can result in 100 percent occupancy with three resident active blocks.

As mentioned in [Occupancy](#), higher occupancy does not always equate to better performance. For example, improving occupancy from 66 percent to 100 percent generally does not translate to a similar increase in performance. A lower occupancy kernel will have more registers available per thread than a higher occupancy kernel, which may result in less register spilling to local memory. Typically, once an occupancy of 50 percent has been reached, additional increases in occupancy do not translate into improved performance. It is in some cases possible to fully cover latency with even fewer warps, notably via instruction-level parallelism (ILP); for discussion, see http://www.nvidia.com/content/GTC-2010/pdfs/2238_GTC2010.pdf.

There are many such factors involved in selecting block size, and inevitably some experimentation is required. However, a few rules of thumb should be followed:

- ▶ Threads per block should be a multiple of warp size to avoid wasting computation on under-populated warps and to facilitate coalescing.
- ▶ A minimum of 64 threads per block should be used, and only if there are multiple concurrent blocks per multiprocessor.
- ▶ Between 128 and 256 threads per block is a better choice and a good initial range for experimentation with different block sizes.
- ▶ Use several (3 to 4) smaller thread blocks rather than one large thread block per multiprocessor if latency affects performance. This is particularly beneficial to kernels that frequently call `__syncthreads()`.

Note that when a thread block allocates more registers than are available on a multiprocessor, the kernel launch fails, as it will when too much shared memory or too many threads are requested.

10.5. Effects of Shared Memory

Shared memory can be helpful in several situations, such as helping to coalesce or eliminate redundant access to global memory. However, it also can act as a constraint on occupancy. In many cases, the amount of shared memory required by a kernel is related to the block size that was chosen, but the mapping of threads to shared memory elements does not need to be one-to-one. For example, it may be desirable to use a 32x32 element shared memory array in a kernel, but because the maximum number of threads per block is 512, it is not possible to launch a kernel with 32x32 threads per block. In such cases, kernels with 32x16 or 32x8 threads can be launched with each thread processing two or four elements, respectively, of the shared memory array. The approach of using a single thread to process multiple elements of a shared memory array can be beneficial even if limits such as threads per block are not an issue. This is because some operations common to each element can be performed by the thread once, amortizing the cost over the number of shared memory elements processed by the thread.

A useful technique to determine the sensitivity of performance to occupancy is through experimentation with the amount of dynamically allocated shared memory, as specified in the third parameter of the execution configuration. By simply increasing

this parameter (without modifying the kernel), it is possible to effectively reduce the occupancy of the kernel and measure its effect on performance.

As mentioned in the previous section, once an occupancy of more than 50 percent has been reached, it generally does not pay to optimize parameters to obtain higher occupancy ratios. The previous technique can be used to determine whether such a plateau has been reached.

Chapter 11.

INSTRUCTION OPTIMIZATION

Awareness of how instructions are executed often permits low-level optimizations that can be useful, especially in code that is run frequently (the so-called hot spot in a program). Best practices suggest that this optimization be performed after all higher-level optimizations have been completed.

11.1. Arithmetic Instructions

Single-precision floats provide the best performance, and their use is highly encouraged. The throughput of individual arithmetic operations is detailed in the *CUDA C Programming Guide*.

11.1.1. Division Modulo Operations

Low Priority: Use shift operations to avoid expensive division and modulo calculations.

Integer division and modulo operations are particularly costly and should be avoided or replaced with bitwise operations whenever possible: If n is a power of 2, (i/n) is equivalent to $(i \gg \log_2(n))$ and $(i \% n)$ is equivalent to $(i \& (n-1))$.

The compiler will perform these conversions if n is literal. (For further information, refer to *Performance Guidelines* in the *CUDA C Programming Guide*).

11.1.2. Reciprocal Square Root

The reciprocal square root should always be invoked explicitly as `rsqrtf()` for single precision and `rsqrt()` for double precision. The compiler optimizes `1.0f/sqrtf(x)` into `rsqrtf()` only when this does not violate IEEE-754 semantics.

11.1.3. Other Arithmetic Instructions

Low Priority: Avoid automatic conversion of doubles to floats.

The compiler must on occasion insert conversion instructions, introducing additional execution cycles. This is the case for:

- ▶ Functions operating on **char** or **short** whose operands generally need to be converted to an **int**
- ▶ Double-precision floating-point constants (defined without any type suffix) used as input to single-precision floating-point computations

The latter case can be avoided by using single-precision floating-point constants, defined with an **f** suffix such as **3.141592653589793f**, **1.0f**, **0.5f**. This suffix has accuracy implications in addition to its ramifications on performance. The effects on accuracy are discussed in [Promotions to Doubles and Truncations to Floats](#). Note that this distinction is particularly important to performance on devices of [compute capability](#) 2.x.

For single-precision code, use of the float type and the single-precision math functions are highly recommended. When compiling for devices without native double-precision support such as devices of compute capability 1.2 and earlier, each double-precision floating-point variable is converted to single-precision floating-point format (but retains its size of 64 bits) and double-precision arithmetic is demoted to single-precision arithmetic.

It should also be noted that the CUDA math library's complementary error function, **erfcf()**, is particularly fast with full single-precision accuracy.

11.1.4. Math Libraries

Medium Priority: Use the fast math library whenever speed trumps precision.

Two types of runtime math operations are supported. They can be distinguished by their names: some have names with prepended underscores, whereas others do not (e.g., **__functionName()** versus **functionName()**). Functions following the **__functionName()** naming convention map directly to the hardware level. They are faster but provide somewhat lower accuracy (e.g., **__sinf(x)** and **__expf(x)**). Functions following **functionName()** naming convention are slower but have higher accuracy (e.g., **sinf(x)** and **expf(x)**). The throughput of **__sinf(x)**, **__cosf(x)**, and **__expf(x)** is much greater than that of **sinf(x)**, **cosf(x)**, and **expf(x)**. The latter become even more expensive (about an order of magnitude slower) if the magnitude of the argument **x** needs to be reduced. Moreover, in such cases, the argument-reduction code uses local memory, which can affect performance even more because of the high latency of local memory. More details are available in the *CUDA C Programming Guide*.

Note also that whenever sine and cosine of the same argument are computed, the **sincos** family of instructions should be used to optimize performance:

- ▶ `__sincosf()` for single-precision fast math (see next paragraph)
- ▶ `sincosf()` for regular single-precision
- ▶ `sincos()` for double precision

The `-use_fast_math` compiler option of `nvcc` coerces every `functionName()` call to the equivalent `__functionName()` call. This switch should be used whenever accuracy is a lesser priority than the performance. This is frequently the case with transcendental functions. Note this switch is effective only on single-precision floating point.

Medium Priority: Prefer faster, more specialized math functions over slower, more general ones when possible.

For small integer powers (e.g., x^2 or x^3), explicit multiplication is almost certainly faster than the use of general exponentiation routines such as `pow()`. While compiler optimization improvements continually seek to narrow this gap, explicit multiplication (or the use of an equivalent purpose-built inline function or macro) can have a significant advantage. This advantage is increased when several powers of the same base are needed (e.g., where both x^2 and x^5 are calculated in close proximity), as this aids the compiler in its common sub-expression elimination (CSE) optimization.

For exponentiation using base 2 or 10, use the functions `exp2()` or `expf2()` and `exp10()` or `expf10()` rather than the functions `pow()` or `powf()`. Both `pow()` and `powf()` are heavy-weight functions in terms of register pressure and instruction count due to the numerous special cases arising in general exponentiation and the difficulty of achieving good accuracy across the entire ranges of the base and the exponent. The functions `exp2()`, `exp2f()`, `exp10()`, and `exp10f()`, on the other hand, are similar to `exp()` and `expf()` in terms of performance, and can be as much as ten times faster than their `pow()/powf()` equivalents.

For exponentiation with an exponent of $1/3$, use the `cbrt()` or `cbrtf()` function rather than the generic exponentiation functions `pow()` or `powf()`, as the former are significantly faster than the latter. Likewise, for exponentiation with an exponent of $-1/3$, use `rcbrt()` or `rcbrtf()`.

Replace `sin(π *<expr>)` with `sinpi(<expr>)`, `cos(π *<expr>)` with `cospi(<expr>)`, and `sincos(π *<expr>)` with `sincospi(<expr>)`. This is advantageous with regard to both accuracy and performance. As a particular example, to evaluate the sine function in degrees instead of radians, use `sinpi(x/180.0)`. Similarly, the single-precision functions `sinpif()`, `cospif()`, and `sincospif()` should replace calls to `sinf()`, `cosf()`, and `sincosf()` when the function argument is of the form `π *<expr>`. (The performance advantage `sinpi()` has over `sin()` is due to simplified argument reduction; the accuracy advantage is because `sinpi()` multiplies by π only implicitly, effectively using an infinitely precise mathematical π rather than a single- or double-precision approximation thereof.)

11.1.5. Precision-related Compiler Flags

By default, the `nvcc` compiler generates IEEE-compliant code for devices of `compute capability` 2.x, but it also provides options to generate code that somewhat less accurate but faster and that is closer to the code generated for earlier devices:

- ▶ **-ftz=true** (denormalized numbers are flushed to zero)
- ▶ **-prec-div=false** (less precise division)
- ▶ **-prec-sqrt=false** (less precise square root)

Another, more aggressive, option is **-use_fast_math**, which coerces every **functionName()** call to the equivalent **__functionName()** call. This makes the code run faster at the cost of diminished precision and accuracy. See [Math Libraries](#).

11.2. Memory Instructions

High Priority: Minimize the use of global memory. Prefer shared memory access where possible.

Memory instructions include any instruction that reads from or writes to shared, local, or global memory. When accessing uncached local or global memory, there are 400 to 600 clock cycles of memory latency.

As an example, the assignment operator in the following sample code has a high throughput, but, crucially, there is a latency of 400 to 600 clock cycles to read data from global memory:

```
__shared__ float shared[32];
__device__ float device[32];
shared[threadIdx.x] = device[threadIdx.x];
```

Much of this global memory latency can be hidden by the thread scheduler if there are sufficient independent arithmetic instructions that can be issued while waiting for the global memory access to complete. However, it is best to avoid accessing global memory whenever possible.

Chapter 12.

CONTROL FLOW

12.1. Branching and Divergence

High Priority: Avoid different execution paths within the same warp.

Any flow control instruction (**if**, **switch**, **do**, **for**, **while**) can significantly affect the instruction throughput by causing threads of the same warp to diverge; that is, to follow different execution paths. If this happens, the different execution paths must be serialized, since all of the threads of a warp share a program counter; this increases the total number of instructions executed for this warp. When all the different execution paths have completed, the threads converge back to the same execution path.

To obtain best performance in cases where the control flow depends on the thread ID, the controlling condition should be written so as to minimize the number of divergent warps.

This is possible because the distribution of the warps across the block is deterministic as mentioned in *SIMT Architecture* of the *CUDA C Programming Guide*. A trivial example is when the controlling condition depends only on $(\text{threadIdx} / \text{WSIZE})$ where **WSIZE** is the warp size.

In this case, no warp diverges because the controlling condition is perfectly aligned with the warps.

12.2. Branch Predication

Low Priority: Make it easy for the compiler to use branch predication in lieu of loops or control statements.

Sometimes, the compiler may unroll loops or optimize out **if** or **switch** statements by using branch predication instead. In these cases, no warp can ever diverge. The programmer can also control loop unrolling using

```
#pragma unroll
```

For more information on this pragma, refer to the *CUDA C Programming Guide*.

When using branch predication, none of the instructions whose execution depends on the controlling condition is skipped. Instead, each such instruction is associated with a per-thread condition code or predicate that is set to true or false according to the controlling condition. Although each of these instructions is scheduled for execution, only the instructions with a true predicate are actually executed. Instructions with a false predicate do not write results, and they also do not evaluate addresses or read operands.

The compiler replaces a branch instruction with predicated instructions only if the number of instructions controlled by the branch condition is less than or equal to a certain threshold: If the compiler determines that the condition is likely to produce many divergent warps, this threshold is 7; otherwise it is 4.

12.3. Loop Counters Signed vs. Unsigned

Low Medium Priority: Use signed integers rather than unsigned integers as loop counters.

In the C language standard, unsigned integer overflow semantics are well defined, whereas signed integer overflow causes undefined results. Therefore, the compiler can optimize more aggressively with signed arithmetic than it can with unsigned arithmetic. This is of particular note with loop counters: since it is common for loop counters to have values that are always positive, it may be tempting to declare the counters as unsigned. For slightly better performance, however, they should instead be declared as signed.

For example, consider the following code:

```
for (i = 0; i < n; i++) {
    out[i] = in[offset + stride*i];
}
```

Here, the sub-expression **stride*i** could overflow a 32-bit integer, so if **i** is declared as unsigned, the overflow semantics prevent the compiler from using some optimizations that might otherwise have applied, such as strength reduction. If instead **i** is declared as signed, where the overflow semantics are undefined, the compiler has more leeway to use these optimizations.

12.4. Synchronizing Divergent Threads in a Loop

High Priority: Avoid the use of `__syncthreads()` inside divergent code.

Synchronizing threads inside potentially divergent code (e.g., a loop over an input array) can cause unanticipated errors. Care must be taken to ensure that all threads are converged at the point where `__syncthreads()` is called. The following example illustrates how to do this properly for 1D blocks:

```
unsigned int imax = blockDim.x * ((nelements + blockDim.x - 1) / blockDim.x);

for (int i = threadIdx.x; i < imax; i += blockDim.x)
{
    if (i < nelements)
    {
        ...
    }

    __syncthreads();

    if (i < nelements)
    {
        ...
    }
}
```

In this example, the loop has been carefully written to have the same number of iterations for each thread, avoiding divergence (`imax` is the number of elements rounded up to a multiple of the block size). Guards have been added inside the loop to prevent out-of-bound accesses. At the point of the `__syncthreads()`, all threads are converged.

Similar care must be taken when invoking `__syncthreads()` from a device function called from potentially divergent code. A straightforward method of solving this issue is to call the device function from non-divergent code and pass a `thread_active` flag as a parameter to the device function. This `thread_active` flag would be used to indicate which threads should participate in the computation inside the device function, allowing all threads to participate in the `__syncthreads()`.

Chapter 13.

DEPLOYING CUDA APPLICATIONS

Having completed the GPU acceleration of one or more components of the application it is possible to compare the outcome with the original expectation. Recall that the initial *assess* step allowed the developer to determine an upper bound for the potential speedup attainable by accelerating given hotspots.

Before tackling other hotspots to improve the total speedup, the developer should consider taking the partially parallelized implementation and carry it through to production. This is important for a number of reasons; for example, it allows the user to profit from their investment as early as possible (the speedup may be partial but is still valuable), and it minimizes risk for the developer and the user by providing an evolutionary rather than revolutionary set of changes to the application.

Chapter 14.

UNDERSTANDING THE PROGRAMMING ENVIRONMENT

With each generation of NVIDIA processors, new features are added to the GPU that CUDA can leverage. Consequently, it's important to understand the characteristics of the architecture.

Programmers should be aware of two version numbers. The first is the [compute capability](#), and the second is the version number of the CUDA Runtime and CUDA Driver APIs.

14.1. CUDA Compute Capability

The *compute capability* describes the features of the hardware and reflects the set of instructions supported by the device as well as other specifications, such as the maximum number of threads per block and the number of registers per multiprocessor. Higher compute capability versions are supersets of lower (that is, earlier) versions, so they are backward compatible.

The compute capability of the GPU in the device can be queried programmatically as illustrated in the **deviceQuery** CUDA Sample. The output for that program is shown in [Figure 12](#). This information is obtained by calling `cudaGetDeviceProperties()` and accessing the information in the structure it returns.

```

C:\WINDOWS\system32\cmd.exe
There is 1 device supporting CUDA

Device 0: "Quadro FX 570"
Major revision number:      1
Minor revision number:      1
Total amount of global memory: 268107776 bytes
Number of multiprocessors:  16
Number of cores:            128
Total amount of constant memory: 65536 bytes
Total amount of shared memory per block: 16384 bytes
Total number of registers available per block: 8192
Warp size:                  32
Maximum number of threads per block: 512
Maximum sizes of each dimension of a block: 512 x 512 x 64
Maximum sizes of each dimension of a grid: 65535 x 65535 x 1
Maximum memory pitch:       262144 bytes
Texture alignment:          256 bytes
Clock rate:                 0.41 GHz
Concurrent copy and execution: Yes

Test PASSED
Press ENTER to exit...

```

Figure 12 Sample CUDA configuration data reported by deviceQuery

The major and minor revision numbers of the compute capability are shown on the third and fourth lines of Figure 12. Device 0 of this system has compute capability 1.1.

More details about the compute capabilities of various GPUs are in *CUDA-Enabled GPUs* and *Compute Capabilities* of the *CUDA C Programming Guide*. In particular, developers should note the number of multiprocessors on the device, the number of registers and the amount of memory available, and any special capabilities of the device.

14.2. Additional Hardware Data

Certain hardware features are not described by the compute capability. For example, the ability to overlap kernel execution with asynchronous data transfers between the host and the device is available on most but not all GPUs with *compute capability* 1.1. In such cases, call `cudaGetDeviceProperties()` to determine whether the device is capable of a certain feature. For example, the `asyncEngineCount` field of the device property structure indicates whether overlapping kernel execution and data transfers is possible (and, if so, how many concurrent transfers are possible); likewise, the `canMapHostMemory` field indicates whether zero-copy data transfers can be performed.

14.3. CUDA Runtime and Driver API Version

The CUDA Driver API and the CUDA Runtime are two of the programming interfaces to CUDA. Their version number enables developers to check the features associated with these APIs and decide whether an application requires a newer (later) version than the one currently installed. This is important because the CUDA Driver API is *backward compatible but not forward compatible*, meaning that applications, plug-ins, and libraries (including the CUDA Runtime) compiled against a particular version of the Driver API will continue to work on subsequent (later) driver releases. However, applications, plug-

ins, and libraries (including the CUDA Runtime) compiled against a particular version of the Driver API may not work on earlier versions of the driver, as illustrated in [Figure 13](#).

Figure 13 Compatibility of CUDA versions

14.4. Which Compute Capability Target

When in doubt about the [compute capability](#) of the hardware that will be present at runtime, it is best to assume a compute capability of 1.0 as defined in the *CUDA C Programming Guide* and *Technical and Feature Specifications*, or a compute capability of 1.3 if double-precision arithmetic is required.

To target specific versions of NVIDIA hardware and CUDA software, use the `-arch`, `-code`, and `-gencode` options of `nvcc`. Code that contains double-precision arithmetic, for example, must be compiled with `arch=sm_13` (or higher compute capability), otherwise double-precision arithmetic will get [demoted to single-precision arithmetic](#).

See [Building for Maximum Compatibility](#) for further discussion of the flags used for building code for multiple generations of CUDA-capable device simultaneously.

14.5. CUDA Runtime

The host runtime component of the CUDA software environment can be used only by host functions. It provides functions to handle the following:

- ▶ Device management
- ▶ Context management
- ▶ Memory management
- ▶ Code module management
- ▶ Execution control
- ▶ Texture reference management
- ▶ Interoperability with OpenGL and Direct3D

As compared to the lower-level CUDA Driver API, the CUDA Runtime greatly eases device management by providing implicit initialization, context management, and device code module management. The C/C++ host code generated by **nvcc** utilizes the CUDA Runtime, so applications that link to this code will depend on the CUDA Runtime; similarly, any code that uses the **cuBLAS**, **cuFFT**, and other CUDA Toolkit libraries will also depend on the CUDA Runtime, which is used internally by these libraries.

The functions that make up the CUDA Runtime API are explained in the *CUDA Toolkit Reference Manual*.

The CUDA Runtime handles kernel loading and setting up kernel parameters and launch configuration before the kernel is launched. The implicit driver version checking, code initialization, CUDA context management, CUDA module management (cubin to function mapping), kernel configuration, and parameter passing are all performed by the CUDA Runtime.

It comprises two principal parts:

- ▶ A C-style function interface (**cuda_runtime_api.h**).
- ▶ C++-style convenience wrappers (**cuda_runtime.h**) built on top of the C-style functions.

For more information on the Runtime API, refer to *CUDA C Runtime* of the *CUDA C Programming Guide*.

Chapter 15.

PREPARING FOR DEPLOYMENT

15.1. Testing for CUDA Availability

When deploying a CUDA application, it is often desirable to ensure that the application will continue to function properly even if the target machine does not have a CUDA-capable GPU and/or a sufficient version of the NVIDIA Driver installed. (Developers targeting a single machine with known configuration may choose to skip this section.)

Detecting a CUDA-Capable GPU

When an application will be deployed to target machines of arbitrary/unknown configuration, the application should explicitly test for the existence of a CUDA-capable GPU in order to take appropriate action when no such device is available. The `cudaGetDeviceCount()` function can be used to query for the number of available devices. Like all CUDA Runtime API functions, this function will fail gracefully and return `cudaErrorNoDevice` to the application if there is no CUDA-capable GPU or `cudaErrorInsufficientDriver` if there is not an appropriate version of the NVIDIA Driver installed. If `cudaGetDeviceCount()` reports an error, the application should fall back to an alternative code path.

A system with multiple GPUs may contain GPUs of different hardware versions and capabilities. When using multiple GPUs from the same application, it is recommended to use GPUs of the same type, rather than mixing hardware generations. The `cudaChooseDevice()` function can be used to select the device that most closely matches a desired set of features.

Detecting Hardware and Software Configuration

When an application depends on the availability of certain hardware or software capabilities to enable certain functionality, the CUDA API can be queried for details about the configuration of the available device and for the installed software versions.

The `cudaGetDeviceProperties()` function reports various features of the available devices, including the [CUDA Compute Capability](#) of the device (see also the *Compute Capabilities* section of the *CUDA C Programming Guide*). See [CUDA Runtime and Driver API Version](#) for details on how to query the available CUDA software API versions.

15.2. Error Handling

All CUDA Runtime API calls return an error code of type `cudaError_t`; the return value will be equal to `cudaSuccess` if no errors have occurred. (The exceptions to this are kernel launches, which return void, and `cudaGetErrorString()`, which returns a character string describing the `cudaError_t` code that was passed into it.) The CUDA Toolkit libraries (`cuBLAS`, `cuFFT`, etc.) likewise return their own sets of error codes.

Since some CUDA API calls and all kernel launches are asynchronous with respect to the host code, errors may be reported to the host asynchronously as well; often this occurs the next time the host and device synchronize with each other, such as during a call to `cudaMemcpy()` or to `cudaDeviceSynchronize()`.

Always check the error return values on all CUDA API functions, even for functions that are not expected to fail, as this will allow the application to detect and recover from errors as soon as possible should they occur. Applications that do not check for CUDA API errors could at times run to completion without having noticed that the data calculated by the GPU is incomplete, invalid, or uninitialized.

The CUDA Toolkit Samples provide several helper functions for error checking with the various CUDA APIs; these helper functions are located in the `samples/common/inc/helper_cuda.h` file in the CUDA Toolkit.

15.3. Building for Maximum Compatibility

Each generation of CUDA-capable device has an associated *compute capability* version that indicates the feature set supported by the device (see [CUDA Compute Capability](#)). One or more [compute capability](#) versions can be specified to the nvcc compiler while building a file; compiling for the native compute capability for the target GPU(s) of the application is important to ensure that application kernels achieve the best possible performance and are able to use the features that are available on a given generation of GPU.

When an application is built for multiple compute capabilities simultaneously (using several instances of the `-gencode` flag to nvcc), the binaries for the specified compute

capabilities are combined into the executable, and the CUDA Driver selects the most appropriate binary at runtime according to the compute capability of the present device. If an appropriate native binary (*cubin*) is not available, but the intermediate *PTX* code (which targets an abstract virtual instruction set and is used for forward-compatibility) is available, then the kernel will be compiled *Just In Time* (JIT) (see [Compiler JIT Cache Management Tools](#)) from the *PTX* to the native *cubin* for the device. If the *PTX* is also not available, then the kernel launch will fail.

Windows

```
nvcc.exe -cbin "C:\vs2008\VC\bin"
-Xcompiler "/EHsc /W3 /nologo /O2 /Zi /MT"
-gencode=arch=compute_10,code=sm_10
-gencode=arch=compute_20,code=sm_20
-gencode=arch=compute_30,code=sm_30
-gencode=arch=compute_35,code=sm_35
-gencode=arch=compute_35,code=compute_35
--compile -o "Release\mykernel.cu.obj" "mykernel.cu"
```

Mac/Linux

```
/usr/local/cuda/bin/nvcc
-gencode=arch=compute_10,code=sm_10
-gencode=arch=compute_20,code=sm_20
-gencode=arch=compute_30,code=sm_30
-gencode=arch=compute_35,code=sm_35
-gencode=arch=compute_35,code=compute_35
-O2 -o mykernel.o -c mykernel.cu
```

Alternatively, the **nvcc** command-line option **-arch=sm_XX** can be used as a shorthand equivalent to the following more explicit **-gencode=** command-line options described above:

```
-gencode=arch=compute_XX,code=sm_XX
-gencode=arch=compute_XX,code=compute_XX
```

However, while the **-arch=sm_XX** command-line option does result in inclusion of a *PTX* back-end target by default (due to the **code=compute_XX** target it implies), it can only specify a single target **cubin** architecture at a time, and it is not possible to use multiple **-arch=** options on the same **nvcc** command line, which is why the examples above use **-gencode=** explicitly.

15.4. Distributing the CUDA Runtime and Libraries

CUDA applications are built against the CUDA Runtime library, which handles device, memory, and kernel management. Unlike the [CUDA Driver](#), the CUDA Runtime guarantees neither forward nor backward binary compatibility across versions. It is therefore best to [redistribute](#) the CUDA Runtime library with the application when using dynamic linking or else to statically link against the CUDA Runtime. This will ensure that the executable will be able to run even if the user does not have the same CUDA Toolkit installed that the application was built against.

Multiple versions of the CUDA Runtime can peacefully coexist in the same application process simultaneously; for example, if an application uses one version of the CUDA Runtime, and a plugin to that application uses a different version, that is perfectly acceptable, as long as the installed NVIDIA Driver is sufficient for both.

Statically-linked CUDA Runtime

The easiest option is to statically link against the CUDA Runtime. This is the default if using `nvcc` to link in CUDA 5.5 and later. Static linking makes the executable slightly larger, but it ensures that the correct version of runtime library functions are included in the application binary without requiring separate redistribution of the CUDA Runtime library.

Dynamically-linked CUDA Runtime

If static linking against the CUDA Runtime is impractical for some reason, then a dynamically-linked version of the CUDA Runtime library is also available. (This was the default and only option provided in CUDA versions 5.0 and earlier.)

To use dynamic linking with the CUDA Runtime when using the `nvcc` from CUDA 5.5 or later to link the application, add the `--cudart=shared` flag to the link command line; otherwise the [statically-linked CUDA Runtime library](#) is used by default.

After the application is dynamically linked against the CUDA Runtime, this version of the runtime library should be [bundled with](#) the application. It can be copied into the same directory as the application executable or into a subdirectory of that installation path.

Other CUDA Libraries

Although the CUDA Runtime provides the option of static linking, the other libraries included in the CUDA Toolkit (cuBLAS, cuFFT, etc.) are available only in dynamically-linked form. As with the [dynamically-linked version of the CUDA Runtime library](#), these libraries should be [bundled with](#) the application executable when distributing that application.

CUDA Toolkit Library Redistribution

The CUDA Toolkit's End-User License Agreement (EULA) allows for redistribution of many of the CUDA libraries under certain terms and conditions. This allows applications that depend on these libraries to redistribute the exact versions of the libraries against which they were built and tested, thereby avoiding any trouble for end users who might have a different version of the CUDA Toolkit (or perhaps none at all) installed on their machines. Please refer to the EULA for details.

This does *not* apply to the NVIDIA Driver; the end user must still download and install an NVIDIA Driver appropriate to their GPU(s) and operating system.

If the CUDA Runtime or other dynamically-linked CUDA Toolkit library is placed in the same directory as the executable, Windows will locate it automatically. On Linux and Mac, the **-rpath** linker option should be used to instruct the executable to search its local path for these libraries before searching the system paths:

Linux/Mac

```
nvcc -I $(CUDA_HOME)/include
      -Xlinker "-rpath '$ORIGIN'" --cudart=shared
      -o myprogram myprogram.cu
```

Windows

```
nvcc.exe -ccbin "C:\vs2008\VC\bin"
          -Xcompiler "/EHsc /W3 /nologo /O2 /Zi /MT" --cudart=shared
          -o "Release\myprogram.exe" "myprogram.cu"
```

It may be necessary to adjust the value of **-ccbin** to reflect the location of your Visual Studio installation.

To specify an alternate path where the libraries will be distributed, use linker options similar to those below:

Linux/Mac

```
nvcc -I $(CUDA_HOME)/include
      -Xlinker "-rpath '$ORIGIN/lib'" --cudart=shared
      -o myprogram myprogram.cu
```

Windows

```
nvcc.exe -ccbin "C:\vs2008\VC\bin"
          -Xcompiler "/EHsc /W3 /nologo /O2 /Zi /MT /DELAY" --cudart=shared
          -o "Release\myprogram.exe" "myprogram.cu"
```

For Linux and Mac, the **-rpath** option is used as before. For Windows, the **/DELAY** option is used; this requires that the application call **SetDllDirectory()** before the first call to any CUDA API function in order to specify the directory containing the CUDA DLLs.

For Windows 8, **SetDefaultDllDirectories()** and **AddDllDirectory()** should be used instead of **SetDllDirectory()**. Please see the MSDN documentation for these routines for more information.

Chapter 16.

DEPLOYMENT INFRASTRUCTURE TOOLS

16.1. Nvidia-SMI

The NVIDIA System Management Interface (**nvidia-smi**) is a command line utility that aids in the management and monitoring of NVIDIA GPU devices. This utility allows administrators to query GPU device state and, with the appropriate privileges, permits administrators to modify GPU device state. **nvidia-smi** is targeted at Tesla and certain Quadro GPUs, though limited support is also available on other NVIDIA GPUs. **nvidia-smi** ships with NVIDIA GPU display drivers on Linux, and with 64-bit Windows Server 2008 R2 and Windows 7. **nvidia-smi** can output queried information as XML or as human-readable plain text either to standard output or to a file. See the **nvidia-smi** documentation for details. Please note that new versions of **nvidia-smi** are not guaranteed to be backward-compatible with previous versions.

16.1.1. Queryable state

ECC error counts

Both correctable single-bit and detectable double-bit errors are reported. Error counts are provided for both the current boot cycle and the lifetime of the GPU.

GPU utilization

Current utilization rates are reported for both the compute resources of the GPU and the memory interface.

Active compute process

The list of active processes running on the GPU is reported, along with the corresponding process name/ID and allocated GPU memory.

Clocks and performance state

Max and current clock rates are reported for several important clock domains, as well as the current GPU performance state (*pstate*).

Temperature and fan speed

The current GPU core temperature is reported, along with fan speeds for products with active cooling.

Power management

The current board power draw and power limits are reported for products that report these measurements.

Identification

Various dynamic and static information is reported, including board serial numbers, PCI device IDs, VBIOS/Inforom version numbers and product names.

16.1.2. Modifiable state

ECC mode

Enable and disable ECC reporting.

ECC reset

Clear single-bit and double-bit ECC error counts.

Compute mode

Indicate whether compute processes can run on the GPU and whether they run exclusively or concurrently with other compute processes.

Persistence mode

Indicate whether the NVIDIA driver stays loaded when no applications are connected to the GPU. It is best to enable this option in most circumstances.

GPU reset

Reinitialize the GPU hardware and software state via a secondary bus reset.

16.2. NVML

The NVIDIA Management Library (NVML) is a C-based interface that provides direct access to the queries and commands exposed via **nvidia-smi** intended as a platform for building 3rd-party system management applications. The NVML API is available on the NVIDIA developer website as part of the Tesla Deployment Kit through a single header file and is accompanied by PDF documentation, stub libraries, and sample applications; see <http://developer.nvidia.com/tesla-deployment-kit>. Each new version of NVML is backward-compatible.

An additional set of Perl and Python bindings are provided for the NVML API. These bindings expose the same features as the C-based interface and also provide backwards compatibility. The Perl bindings are provided via CPAN and the Python bindings via PyPI.

All of these products (**nvidia-smi**, NVML, and the NVML language bindings) are updated with each new CUDA release and provide roughly the same functionality.

See <http://developer.nvidia.com/nvidia-management-library-nvml> for additional information.

16.3. Cluster Management Tools

Managing your GPU cluster will help achieve maximum GPU utilization and help you and your users extract the best possible performance. Many of the industry's most

popular cluster management tools now support CUDA GPUs via NVML. For a listing of some of these tools, see <http://developer.nvidia.com/cluster-management>.

16.4. Compiler JIT Cache Management Tools

Any PTX device code loaded by an application at runtime is compiled further to binary code by the device driver. This is called *just-in-time compilation (JIT)*. Just-in-time compilation increases application load time but allows applications to benefit from latest compiler improvements. It is also the only way for applications to run on devices that did not exist at the time the application was compiled.

When JIT compilation of PTX device code is used, the NVIDIA driver caches the resulting binary code on disk. Some aspects of this behavior such as cache location and maximum cache size can be controlled via the use of environment variables; see *Just in Time Compilation* of the *CUDA C Programming Guide*.

16.5. CUDA_VISIBLE_DEVICES

It is possible to rearrange the collection of installed CUDA devices that will be visible to and enumerated by a CUDA application prior to the start of that application by way of the **CUDA_VISIBLE_DEVICES** environment variable.

Devices to be made visible to the application should be included as a comma-separated list in terms of the system-wide list of enumerable devices. For example, to use only devices 0 and 2 from the system-wide list of devices, set **CUDA_VISIBLE_DEVICES=0,2** before launching the application. The application will then enumerate these devices as device 0 and device 1, respectively.

Appendix A.

RECOMMENDATIONS AND BEST PRACTICES

This appendix contains a summary of the recommendations for optimization that are explained in this document.

A.1. Overall Performance Optimization Strategies

Performance optimization revolves around three basic strategies:

- ▶ Maximizing parallel execution
- ▶ Optimizing memory usage to achieve maximum memory bandwidth
- ▶ Optimizing instruction usage to achieve maximum instruction throughput

Maximizing parallel execution starts with structuring the algorithm in a way that exposes as much data parallelism as possible. Once the parallelism of the algorithm has been exposed, it needs to be mapped to the hardware as efficiently as possible. This is done by carefully choosing the execution configuration of each kernel launch. The application should also maximize parallel execution at a higher level by explicitly exposing concurrent execution on the device through streams, as well as maximizing concurrent execution between the host and the device.

Optimizing memory usage starts with minimizing data transfers between the host and the device because those transfers have much lower bandwidth than internal device data transfers. Kernel access to global memory also should be minimized by maximizing the use of shared memory on the device. Sometimes, the best optimization might even be to avoid any data transfer in the first place by simply recomputing the data whenever it is needed.

The effective bandwidth can vary by an order of magnitude depending on the access pattern for each type of memory. The next step in optimizing memory usage is therefore to organize memory accesses according to the optimal memory access patterns. This optimization is especially important for global memory accesses, because latency of access costs hundreds of clock cycles. Shared memory accesses, in counterpoint, are usually worth optimizing only when there exists a high degree of bank conflicts.

As for optimizing instruction usage, the use of arithmetic instructions that have low throughput should be avoided. This suggests trading precision for speed when it does

not affect the end result, such as using intrinsics instead of regular functions or single precision instead of double precision. Finally, particular attention must be paid to control flow instructions due to the SIMT (single instruction multiple thread) nature of the device.

Appendix B.

NVCC COMPILER SWITCHES

B.1. nvcc

The NVIDIA **nvcc** compiler driver converts **.cu** files into C for the host system and CUDA assembly or binary instructions for the device. It supports a number of command-line parameters, of which the following are especially useful for optimization and related best practices:

- ▶ **-arch=sm_13** or higher is required for double precision. See [Promotions to Doubles and Truncations to Floats](#).
- ▶ **-maxrregcount=N** specifies the maximum number of registers kernels can use at a per-file level. See [Register Pressure](#). (See also the **__launch_bounds__** qualifier discussed in *Execution Configuration* of the *CUDA C Programming Guide* to control the number of registers used on a per-kernel basis.)
- ▶ **--ptxas-options=-v** or **-Xptxas=-v** lists per-kernel register, shared, and constant memory usage.
- ▶ **-ftz=true** (denormalized numbers are flushed to zero)
- ▶ **-prec-div=false** (less precise division)
- ▶ **-prec-sqrt=false** (less precise square root)
- ▶ **-use_fast_math** compiler option of **nvcc** coerces every **functionName()** call to the equivalent **__functionName()** call. This makes the code run faster at the cost of diminished precision and accuracy. See [Math Libraries](#).
